Vitamin D (where D represents D₂ or D₃) is biologically inert and is metabolized in the liver to 25-hydroxyvitamin D [25(OH)D], the major circulating form of vitamin D. 25(OH)D is activated in the kidneys to 1,25-dihydroxyvitamin D [1,25(OH)₂D], which regulates calcium, phosphorus, and bone metabolism.⁵

CALCIUM HOMEOSTASIS

Calcium is regulated by a combination of bone exchange, renal excretion, and intestinal absorption. Decreased ionized calcium increases parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D₂, both of which increase osteoclastic activity and thus stimulate bone resorption. Renal excretion of calcium is regulated by PTH and vitamin D, which increase distal tubular reabsorption of calcium, and by calcitonin, which inhibits calcium reabsorption. Intestinal absorption of calcium depends primarily on 1,25-dihydroxyvitamin D₂, which stimulates calcium absorption from all parts of the small intestine.⁶

Hypocalcemia

Disorders associated with hypocalcemia can be classified into disorders related to vitamin D or PTH.

Disorders Related to Vitamin D Deficiency

Vitamin D Deficiency. Hypocalcemia is a frequently found feature of vitamin D deficiency. The common causes of vitamin D deficiency are listed in [Box 106-1](#). Lack of exposure to sunlight impairs endogenous vitamin D synthesis. Because vitamin D is a fat-soluble vitamin, poor intake of food products containing fatty substances results in nutritional osteomalacia. Gastrectomy may result in dietary deficiency from avoiding the consumption of fatty products and/or malabsorption of vitamin D, as noted with Billroth type II surgery, in which a vitamin D-absorbing bowel segment is bypassed. Deficiency of the bile salts also impairs vitamin D absorption. Small bowel diseases, laxative abuse, and certain anticonvulsants (phenytoin) can interfere with absorption, and urinary loss of vitamin D is associated with Fanconi's syndrome and nephrotic syndrome.⁷ Because the hepatic formation of 25(OH) vitamin D from vitamin D is not tightly controlled and depends primarily on the availability of vitamin D, the serum level of 25(OH) vitamin D₃ is utilized as a measurement of the body stores of vitamin D; low levels of 25(OH) vitamin D indicate vitamin D deficiency.¹

Impaired Metabolism of Vitamin D. Antiepileptic drugs, including carbamazepine, phenobarbital, and phenytoin, may cause hypocalcemia associated with low levels of circulating 25(OH) vitamin D caused by the induction of microsomal enzymes in the liver. Low

circulating levels of 25(OH) vitamin D have also been observed in patients with hepatic failure due to the reduced transformation of vitamin D to 25(OH) vitamin D.⁸

Dietary calcium deprivation increases the clearance and inactivation of 25(OH) vitamin D and causes vitamin D deficiency. This variety of vitamin D deficiency may be caused by secondary hyperparathyroidism, which augments renal synthesis of 1,25(OH)₂ vitamin D and in turn, enhances the degradation of 25(OH) vitamin D to inactive metabolites. Hypothetically, this mechanism may account for vitamin D deficiency in clinical states of calcium malabsorption, including gastrointestinal diseases, anticonvulsant therapy (e.g., phenytoin), and the use of drugs such as colchicine, fluoride, and theophylline. Likewise, increased intake of foods rich in phytate, oxalate, and citrate that chelate calcium in the gastrointestinal tract and render it nonabsorbable may cause vitamin D deficiency.^{1,9}

Vitamin D–dependent rickets type I (VDDR-1), also designated as *pseudovitamin D deficiency*, is inherited as an autosomal recessive disorder in which there is a deficiency in 25(OH) vitamin D-1 α -hydroxylase in the proximal tubules due to defects in the 1 α -hydroxylase gene. It is manifested by early hypocalcemia, hypophosphatemia, severe secondary hyperparathyroidism, and severe rickets. Serum 1,25(OH)₂ vitamin D is undetectable or very low, whereas 25(OH) vitamin D levels are normal. VDDR-1 can be reversed completely by the administration of pharmacologic doses of vitamin D or physiologic doses of 1,25(OH)₂ vitamin D. Linkage analysis in families with VDDR-1 has mapped the disease locus to chromosome 12q13-14.¹⁰

End Organ Resistance to 1,25(OH)₂ Vitamin D. Hypocalcemia refractory to 1,25(OH)₂ vitamin D₃ has been described as type II vitamin D–dependent rickets, also known as hereditary 1,25(OH)₂ vitamin D₃–resistant rickets. This familial disorder is inherited by autosomal recessive transmission and is characterized by hypocalcemia, impaired intestinal absorption of calcium, rickets, and alopecia, which reflects a defect in the physiologic action of 1,25(OH)₂ vitamin D in the skin. In contrast to VDDR-1, in type II, the serum 1,25(OH)₂ vitamin D levels are elevated, and the patients either respond to pharmacologic doses of 1,25(OH)₂ vitamin D₃ or do not respond at all. Mutations of vitamin D receptor genes have been identified in these patients.

Disorders Related to Parathyroid Hormone**Reduced Production of PTH**

Hypoparathyroidism. Hypoparathyroidism is a disorder characterized by hypocalcemia and hyperphosphatemia due to deficient or absent secretion of PTH.

Hypoparathyroidism is a common cause of hypocalcemia. It can present as paresthesias, muscle spasms (i.e., tetany), and seizures. However, mild chronic hypoparathyroidism may cause hypocalcemia so gradually that the only symptoms may be visual impairment from cataracts after years of hypoparathyroidism. Hypoparathyroidism may be either an acquired abnormality designated as secondary hypoparathyroidism or primary hypoparathyroidism, also known as *idiopathic hypoparathyroidism*.

Secondary Hypoparathyroidism. Postoperative hypoparathyroidism may result from the removal of the parathyroid glands or the traumatic interruption of their blood supply. Hypocalcemia following parathyroid adenoma excision results from the functional suppression and hypofunctioning of the remaining normal glands and is usually transient. “Hungry bone” syndrome can develop following parathyroidectomy in patients with markedly elevated preoperative PTH levels. Decreased postoperative levels of PTH cause a “rebound” recalcification of the bones secondary to unbalanced osteoblast and osteoclast activity. This results in profound hypocalcemia, hypophosphatemia, and elevated alkaline phosphatase. Similarly, hypocalcemia has been reported to occur in 15% of patients after thyroidectomy.¹¹

Hypoparathyroidism may be a component of multiple endocrine dysfunctions, including adrenal insufficiency, pernicious anemia, thalassemia, and Wilson's disease. In the last two disorders, the deposition of iron and copper, respectively, in the parathyroid glands are the likely underlying mechanisms.¹²

Hypocalcemia may occur in magnesium depletion, likely secondary to the diminished release of PTH.¹³ Hypomagnesemia has also been reported to induce skeletal resistance to PTH.¹⁴ The magnesium level should always be checked during the workup of profound refractory hypocalcemia. It is speculated that magnesium depletion may impair the activity of calcium pumps and thus alter the distribution of calcium between the extracellular and the intracellular spaces.

Hypocalcemia in association with hypomagnesemia has been reported in 60% of patients with severe acute respiratory distress syndrome.¹⁵ Hypocalcemia may follow the therapeutic use of magnesium sulfate (e.g., in preeclampsia) secondary to magnesium-induced suppression of PTH. Aminoglycosides and cytotoxic agents may exert toxic effects on parathyroid glands, leading to hypocalcemia,^{1,13} and symptomatic hypoparathyroidism has been observed in association with HIV infection.¹

Primary (Idiopathic) Hypoparathyroidism. Primary hypoparathyroidism may occur in association with other endocrine disorders or as an isolated entity. The latter is termed *isolated hypoparathyroidism* and may occur as a sporadic or familial disorder, inherited as either the autosomal dominant or recessive forms.¹⁴

Aplasia or hypoplasia of the parathyroid glands is most commonly caused by the DiGeorge or velocardiofacial syndrome, which is associated with deletions in chromosome 22q11.2. Most cases are sporadic, but familial cases with autosomal dominant inheritance have been reported. The affected patients have abnormalities in the organs derived from the third and fourth branchial arches, including the parathyroid glands, thymus, and the outflow tract of the heart. These patients typically present in the first week after birth with signs of hypocalcemia, such as tetany and seizures. They have characteristic facial features, including an upturned nose and a widened distance between the inner canthi (telecanthus), with a short palpebral fissure. Cardiac defects include truncus arteriosus, tetralogy of Fallot, or interrupted aortic arch, and thymic hypoplasia leads to immune deficiencies. CATCH 22 syndrome is an acronym for cardiac defects, abnormal facies, thymic hypoplasia, cleft palate, and hypocalcemia caused by chromosome 22q11 deletions.¹⁶

Autoimmune hypoparathyroidism is commonly a part of polyglandular autoimmune syndrome type I, which is a familial syndrome. It occurs during childhood and is inherited as an autosomal recessive trait. It can present as hypoparathyroidism in the absence of the two other disorders. Adrenal insufficiency is a late phenomenon in this syndrome. The acronym APECED stands for *autoimmune polyglandular endocrinopathy with candidiasis and ectodermal dystrophy*,

including vitiligo, alopecia, nail dystrophy, enamel hypoplasia of the teeth, and corneal opacities.¹⁷

Hypoparathyroidism has been reported in association with two mitochondrial cytopathies: Kearns-Sayre syndrome and Kenny-Caffey syndrome.¹⁸

Impaired Action of PTH Due to Peripheral Resistance

Pseudohypoparathyroidism. Pseudohypoparathyroidism is a rare inheritable disorder characterized by mental retardation, moderate obesity, short stature, brachydactyly with short metacarpal and metatarsal bones, exostoses, radius curvus, and an expressionless face.¹⁹ The biochemical abnormalities are hypocalcemia and hyperphosphatemia.

Calcitonin. Calcitonin binds to specific cell membrane receptors on bone-resorbing osteoclasts and depresses their activity. In this regard, it antagonizes the effect of PTH on bone.

Medullary carcinoma of the thyroid is derived from parafollicular cells of the ultimobranchial organ, which secretes calcitonin. It may present as a familial and autosomal dominant or sporadic disorder. Patients with this tumor have high circulating levels of calcitonin, and hypocalcemia has been reported in some patients.²⁰

Hypocalcemia has been described in critically ill patients admitted to intensive care units (ICUs).²¹ The degree of hypocalcemia correlates with the severity of the disease, and it is most commonly detected in patients who are septic. The mechanism of this abnormality is unknown. Circulating levels of calcitonin precursors (CTpr) increase up to several thousand-fold in response to microbial infections, and such increases correlate with the severity of the infection and mortality. The relationship between the elevated CTpr and the emergence of hypocalcemia requires further investigation.²²

Bisphosphonates. Hypocalcemia has been reported in patients with bone metastases of solid tumors who were treated with pamidronate²³ and in a patient treated with alendronate for osteoporosis. In both cases, bisphosphonate induced skeletal resistance, and PTH was proposed as a possible mechanism. Hypomagnesemia may cause hypocalcemia by a similar mechanism.²⁴

Rapid Removal of Calcium from the Circulation

Malignant Neoplasms. Hypocalcemia may develop in patients with malignant neoplasms in association with osteoblastic bone-forming metastases, most commonly cancer of the prostate and breast. These lesions may lead to rapid deposition of minerals in the newly formed matrix, thus causing hypocalcemia.

Hyperphosphatemia. The various causes of hyperphosphatemia that may lead to hypocalcemia are listed in Box 106-2. The oral or intravenous (IV) administration of phosphate lowers serum calcium concentrations in normal animals and hypercalcemic human subjects, which forms the basis for the clinical use of phosphate administration in states of hypercalcemia. The association of hyperphosphatemia and

hypocalcemia has been reported to occur in a variety of circumstances. Hyperphosphatemia has been observed in persons ingesting large quantities of phosphate-containing laxatives or receiving enemas with phosphate. Hyperphosphatemia and hypocalcemia with tetany may develop in infants fed cow's milk, which contains 1220 mg of calcium and 940 mg of phosphorus per liter (human milk contains 340 mg of calcium and 150 mg of phosphorus per liter).^{25,26} The mechanism responsible for lowering serum calcium concentrations by the administration of phosphate is not entirely understood. One possibility is that the decrease in serum calcium concentration is caused by the deposition of calcium phosphate in the bone, soft tissues, or both.

In chronic renal failure, an increase in serum phosphorus concentration is observed when the glomerular filtration rate is 30 mL/min or less, and hyperphosphatemia is a common accompaniment of acute renal failure.

In patients undergoing chemotherapy for neoplastic diseases, particularly of lymphatic origin, large quantities of phosphates may be released into the circulation as a result of cytolysis. Spontaneous tumor lysis may cause hyperphosphatemia and, consequently, hypocalcemia.

Acute Pancreatitis. The hypocalcemia associated with acute pancreatitis is not well understood. The precipitation of calcium soaps in the abdominal cavity, which results from the release of lipolytic enzymes and fat necrosis, has been suggested as the mechanism of hypocalcemia. Recently, endotoxemia has also been implicated.²⁷

Citrate, Bicarbonate, and Poisoning with Ethylene Glycol. Citrate is present in stored blood products (such as plasma and platelets) as an anticoagulant that exerts its action through the binding of ionized calcium. Patients receiving a massive transfusion frequently experience hypocalcemia; however, this is usually transient secondary to rapid hepatic metabolism of citrate.²⁸ Ionized hypocalcemia (with a normal total calcium concentration) can lead to tetany, myocardial dysfunction, or hypotension. Bicarbonate may directly complex calcium or may increase protein binding of calcium from the resulting alkalosis. Low serum ionized calcium may be a complication of ethylene glycol (antifreeze) poisoning because of calcium binding by oxalic acid, which is the metabolite of this poison.

Clinical Consequences of Hypocalcemia

The clinical presentation of hypocalcemia depends on its severity, the rapidity of the fall in serum calcium concentration, the age of the patient, the chronicity of the hypocalcemia, and comorbid conditions.

Most infants with hypocalcemia are asymptomatic. Among those who become symptomatic, the characteristic sign is increased neuromuscular irritability. Generalized or focal clonic seizures may be the first indication of hypocalcemia. Other manifestations may include stridor caused by laryngospasms and wheezing caused by bronchospasms. Vomiting may be caused by pylorospasm.

Neuromuscular manifestations of hypocalcemia in adults are variable (Box 106-3). The characteristic symptom is tetany, which includes perioral numbness and tingling, paresthesias in the extremities, carpopedal spasm, laryngospasm, and focal and generalized seizures. The spasms of the diaphragm and the intercostal muscles may cause respiratory arrest and asphyxia.

The characteristic physical findings in patients with hypocalcemia that are indicative of latent tetany are Trousseau's sign (carpal spasm) and Chvostek's sign (facial muscle contraction). Visual impairment may be caused acutely by papilledema, whereas when chronic hypocalcemia is due to hypoparathyroidism, it usually causes cataracts.

Acute hypocalcemia may be associated with hypotension, which is frequently aggravated by the absence of compensatory reflex tachycardia. The typical electrocardiogram (ECG) change in hypocalcemic patients is prolongation of the QT interval and is associated with a variety of ventricular arrhythmias, most characteristically torsades de pointes. These abnormalities can be reversed with calcium replacement. Calcium therapy significantly shortens the repolarization intervals and decreases the frequency of the premature ventricular contractions.²⁹ Chronic hypocalcemia may cause dilated cardiomyopathy, and partial

calcium can be provided as a drip of 100 to 200 mg of elemental calcium given over several hours until oral calcium takes over. Extravasation of calcium infusions should be avoided because of local irritation and thrombophlebitis.

Chronic treatment of hypocalcemia with oral calcium should follow IV therapy in patients with chronic hypocalcemia due to irreversible causes such as hypoparathyroidism. Oral calcium administration constitutes the best initial therapy in mild cases of hypocalcemia. The commonly used preparations are in tablet form: calcium lactate, 300 mg (60 mg of elemental calcium); chewable calcium gluconate, 1 g (90 mg of elemental calcium); calcium carbonate (Os-Cal; 250 mg of elemental calcium); calcium carbonate, 650 mg (250 mg of elemental calcium); and calcium citrate, 950 mg (200 mg of elemental calcium).

Oral calcium may be used in patients for whom the diagnosis of irreversible hypoparathyroidism has not been firmly established. In patients who fail to respond to oral calcium, vitamin D in large doses is the only available treatment. Both hypoparathyroidism and pseudohypoparathyroidism respond to physiologic doses of 1,25(OH)₂ vitamin D₃ and 1α(OH) vitamin D₃, with restoration of the serum calcium concentrations to normal. Calcitriol is marketed as Rocaltrol and is dispensed in capsules containing 0.25 or 1.0 μg. Chlorothiazides may enhance the calcemic action of vitamin D and its analogs, whereas furosemide may aggravate the hypocalcemia through its hypercalciuric action.

Patients in whom hypocalcemia is associated with hypomagnesemia respond poorly to IV calcium, but the serum calcium concentration is restored to normal levels with correction of the hypomagnesemia.

Symptoms rarely develop in patients with chronic renal failure and hypocalcemia. However, very often, reduction of elevated serum phosphorus with phosphate-binding antacids causes an increase in the serum calcium concentrations.

Hypocalcemia associated with osteomalacia resulting from vitamin D deficiency is rarely symptomatic. It usually responds to physiologic doses of vitamin D and increased oral calcium.

Hypercalcemia

Primary hyperparathyroidism and malignancy account for 80% to 90% of all cases of hypercalcemia.³¹ Primary hyperparathyroidism is the leading cause of hypercalcemia in the outpatient setting, with an incidence of 1% in the normal population.³² Hypercalcemia is most often detected in routinely tested blood specimens. Malignancy is the prevalent cause of hypercalcemia in hospitalized patients. The most common cause of iatrogenic hypercalcemia is milk-alkali syndrome (MAS), which ranks third after malignancy and hyperparathyroidism and accounts for 10% to 15% of the cases of hypercalcemia. The over-the-counter access to the generic brands of calcium carbonate and their widespread use for heartburn and osteoporosis may be an underlying cause for the rise in the incidence of MAS.³³

Hypercalcemia presents a challenge to every clinician. In some instances, the cause of hypercalcemia is self-evident on the basis of circumstantial clinical findings, whereas extensive efforts are required to establish the etiology in other situations. The important causes of hypercalcemia are listed in [Box 106-3](#).

Hyperparathyroidism

Since primary hyperparathyroidism is a surgically curable disease, prompt and accurate diagnosis is important.¹ The disease is more common in females than in males; the incidence increases in women after menopause but is less frequent in older men. Primary hyperparathyroidism is caused by a solitary adenoma in 80% to 85% of patients, multigland hyperplasia in 15% to 20%, and parathyroid carcinoma in less than 1% of patients.³⁴

The morphologic differentiation between adenomas and hyperplasia can be very difficult. The presence of a capsule and a rim of compressed normal gland tissue around the periphery of an adenoma may be helpful in making a definitive diagnosis. The persistence or

recovery of cardiac function has been reported after restoration of normocalcemia.³⁰

Treatment of Hypocalcemia

Symptomatic hypocalcemia generally responds promptly to the IV administration of calcium. The commonly used preparations are 10% calcium gluconate and 10% calcium chloride. Treatment should be instituted immediately, as delay can further aggravate tetany and lead to generalized seizures and even cardiac arrest.

The IV administration of 100 to 200 mg elemental calcium (5 to 10 mEq) should be slow to avoid complications. The administration of

recurrence of hypercalcemia after surgery for a purported adenoma should raise the suspicion of parathyroid hyperplasia. If more than one gland shows histologic features of hyperplasia, then a subtotal or total parathyroidectomy is recommended. Some patients with primary hyperparathyroidism have especially pronounced hypercalciuria despite a very mild degree of hypercalcemia and minimal or no bone disease. In patients with primary hyperparathyroidism, a very strong positive correlation was found between $1,25(\text{OH})_2$ vitamin D_3 in the serum and urinary calcium excretion. Patients with nephrolithiasis and hypercalcemia had circulating levels of $1,25(\text{OH})_2$ vitamin D_3 higher than those present in hyperparathyroid patients without renal stones. The reason for this difference in the $1,25(\text{OH})_2$ vitamin D_3 levels is unknown but stresses the importance of vitamin D metabolism in the clinical presentation of primary hyperparathyroidism.¹

Hyperparathyroidism is associated with multiple endocrine neoplasia (MEN) type I and II, both of which are inherited in an autosomal dominant fashion. MEN I syndrome is characterized by parathyroid hyperplasia, neuroendocrine tumors of the pancreas and duodenum, and pituitary adenomas. MEN II syndrome includes MEN IIA and MEN IIB; MEN IIA syndrome is characterized by pheochromocytoma, parathyroid hyperplasia, and medullary thyroid cancer, while MEN IIB syndrome includes medullary thyroid cancer, pheochromocytoma, mucosal neuromas, and a distinct physical appearance but does not involve hyperparathyroidism. Establishing the diagnosis of hyperparathyroidism associated with MEN syndrome has important surgical implications.^{35,36} The diagnosis of primary hyperparathyroidism requires the findings of elevated serum calcium and intact parathyroid hormone (iPTH) levels, normal renal function, and normal or increased urinary calcium excretion. Patients presenting with bone, renal, gastrointestinal, or neuromuscular symptoms are considered symptomatic and are best treated with surgical excision. Asymptomatic patients with primary hyperparathyroidism are surgical candidates if they meet the criteria established by the National Institutes of Health (NIH Criteria for Parathyroidectomy).^{37,38} These criteria include markedly elevated serum calcium (>12 mg/dL), a history of life-threatening hypercalcemia, creatinine clearance reduced by 30%, markedly elevated 24-h urine calcium (>400 mg/d), nephrolithiasis, age <50 years, osteitis fibrosa cystica, and substantially reduced bone mass (>2 standard deviations below control).

Recent advances in imaging allow preoperative or intraoperative localization of parathyroid adenomas, thus permitting a minimally invasive surgical approach. Options include the $^{99\text{m}}\text{Tc}$ -sestamibi scan with or without single-photon emission computed tomography, computed tomography, ultrasonography, magnetic resonance imaging, and thallium-201/technetium pertechnetate scanning. The most promising preoperative adjunct, however, seems to be intraoperative PTH monitoring.³⁹

Familial hypocalciuric hypercalcemia is an unusual form of parathyroid hyperplasia with autosomal dominant transmission. It is usually asymptomatic and incidentally diagnosed by an elevated serum calcium level and confirmed by a low urinary calcium level. The clinical course is relatively benign, with an absence of nephrolithiasis and an infrequent occurrence of pancreatitis and chondrocalcinosis, and it usually requires no specific therapy.

Malignancy Associated with Hypercalcemia

Hypercalcemia is most commonly associated with tumors of the lung, breast, kidney, and ovary and hematologic malignancies. Two main mechanisms are known to mediate the hypercalcemia of malignancy: local and humoral.⁴⁰ The local mechanism is manifested by the presence of osteolytic lesions in the skeleton. The malignant cells may act to destroy the bone directly; however, even local osteolysis is mediated by activated osteoclasts in most instances. The humoral factor most commonly associated with hypercalcemia of malignancy is parathyroid hormone-related protein (PTHrP).⁴¹ PTHrP induces osteoclastic resorption of bone, increases tubular reabsorption of calcium in the kidneys, and inhibits osteoblast activity through the action of cytokines such as interleukin-6.⁴² These factors explain why serum calcium

rises rapidly in cancer patients in contrast to the gradual rise in hyperparathyroidism.

Multiple Myeloma and Hypercalcemia

Hypercalcemia occurs in approximately one-third of patients with myeloma. Osteolytic bone lesions are the most common skeletal radiographic findings. The bone destruction in myeloma is mediated by osteoclasts that accumulate adjacent to the collections of myeloma cells. This relationship between myeloma cells and osteoclasts explains the rapid destruction of bone in this malignancy.^{43,44}

Vitamin D Intoxication and Hypercalcemia

All patients receiving vitamin D, other than in small doses, may develop hypercalcemia, with the attendant risk of renal failure. The appearance of hypercalcemia in hypoparathyroid patients receiving pharmacologic doses of either ergocalciferol (vitamin D_2) or dihydroxycholesterol 3 is unpredictable, because the margin between normocalcemic and hypercalcemic doses of the vitamin is very narrow. Hypercalcemia associated with vitamin D intoxication may be present from 1 to 6 weeks after discontinuation of treatment, and normocalcemia may persist for an additional 4 months without any treatment. The toxic effect of vitamin D excess is associated with a high circulating level of $25(\text{OH})$ vitamin D_3 , which is continuously produced by the liver from the adipose tissue stores of vitamin D. The serum level of $1,25(\text{OH})_2$ vitamin D_3 is not generally elevated and may even be reduced; however, free non-protein-bound $1,25(\text{OH})_2$ vitamin D_3 levels may be elevated. Hypercalcemia associated with $1,25(\text{OH})_2$ vitamin D_3 administration, however, is much more short lived (3 to 7 days).⁴⁵

Various factors may alter the response to vitamin D. The inhibitory effect of estrogens on bone resorption may be absent after menopause, which allows more calcium to be released from bone for any given dose of vitamin D. The administration of corticosteroids may reduce the effect of vitamin D; in fact, corticosteroids may be used to treat vitamin D intoxication. The most important precaution in preventing the complications of vitamin D intoxication is to measure serum calcium concentrations frequently in these patients. Likewise, the presence of excessive hypercalciuria, even in the absence of hypercalcemia, is a risk factor for nephrocalcinosis and renal failure. Thus, monitoring of urinary calcium excretion in these circumstances is recommended as well.

Vitamin A Intoxication and Hypercalcemia

Hypercalcemia is also associated with excessive intake of vitamin A,⁴⁶ which is readily available in various pharmaceutical preparations. Isotretinoin, a derivative of vitamin A that is effective in the treatment of severe acne, has been reported as a cause of hypercalcemia. The main symptom of vitamin A intoxication is painful swelling in the extremities. Prolonged hypercalcemia in this condition has also been associated with nephrocalcinosis and the impairment of renal function.

Sarcoidosis and Hypercalcemia

Sarcoidosis is a systemic granulomatous inflammatory disease characterized by noncaseating granulomas in multiple organ systems. Hypercalciuria is the most common defect in calcium metabolism; however, hypercalcemia occurs in approximately 5% of patients.⁴⁷

Plasma levels of $1,25(\text{OH})_2$ vitamin D_3 have been found to be increased in patients with sarcoidosis and hypercalcemia, a finding that accounts for the abnormal calcium metabolism in this disease. In most of the patients, glucocorticoids can normalize the serum levels of calcium and $1,25(\text{OH})_2$ vitamin D_3 . Low levels of serum immunoreactive PTH have been found in patients with sarcoidosis, regardless of the presence or absence of hypercalcemia.⁴⁷

Hyperthyroidism, Hypothyroidism, and Hypercalcemia

Hyperthyroidism is associated with accelerated bone turnover, which is caused by the direct stimulation of bone cells by the high thyroid

hormone concentrations.⁴⁸ Biochemical markers of bone formation and resorption (osteocalcin, alkaline phosphatase, bone-specific alkaline phosphatase, and urinary collagen pyridinoline) are elevated in hyperthyroid patients, indicating increased bone turnover in favor of osteoclastic bone resorption.⁴⁹ The resultant hypercalcemia may be reversed by antithyroid therapy.⁵⁰

Serum calcium and phosphate levels are normal and alkaline phosphatase is low in the vast majority of patients with hypothyroidism; however, some patients may manifest hypercalcemia. The calcium balance in patients with hypothyroidism tends to be positive as a result of increased intestinal absorption and reduced urinary excretion. Both changes predispose to the development of hypercalcemia. Bone turnover in hypothyroid patients is reduced.

Adrenal Insufficiency and Hypercalcemia

Hypercalcemia is a common abnormality in adrenal insufficiency, although the mechanism is not well understood. One study has indicated that the increase in serum calcium concentration is due to an increase in the protein-bound fraction of serum calcium that results from the accompanying volume depletion. Volume depletion may also cause an increase in the renal tubular reabsorption of calcium, and vitamin D's enhancement of calcium absorption from the intestine may be greater in the absence of glucocorticoid hormone.⁵¹

Idiopathic Infantile Hypercalcemia

Idiopathic infantile hypercalcemia (IIH) is a rare cause of hypercalcemia in the first year of life and is a diagnosis of exclusion. Clinical features include vomiting, irritability, constipation, increased thirst, and failure to thrive.⁵² While the pathophysiology of IIH remains unclear, some authors attribute the hypercalcemia to intestinal vitamin D sensitivity that leads to increased calcium absorption and contributes to persistent hypercalciuria.⁵³ Treatment options for IIH include corticosteroids, low-calcium diet, calcitonin, and cellulose phosphate. Patients usually experience spontaneous resolution of hypercalcemia.

Immobilization and Hypercalcemia

Immobilization may be associated with excessive loss of bone minerals, hypercalcemia, and rapidly developing osteoporosis. The lack of postural mechanical stimuli to the skeleton disturbs the balance between bone formation and resorption, thus leading to the loss of bone mass. Usually, the amount of calcium released from bone is excreted in the urine and does not increase the serum calcium concentrations. Due to a reduced ability to excrete calcium in the urine, patients with pre-existing renal impairment are prone to develop immobilization hypercalcemia.⁵⁴

Milk-Alkali Syndrome

MAS may occur in patients who ingest large amounts of milk and alkali as a therapy to relieve the symptoms of peptic ulcers. This syndrome is characterized by hypercalcemia, hyperphosphatemia, alkalosis, metastatic calcifications, and progressive renal failure. The ingestion of large amounts of calcium carbonate (at least 4 to 5 g daily) and absorbable alkali is a prerequisite for establishing the diagnosis.³³ For hypercalcemia to develop, calcium intake must be excessive, but the inability to excrete this excessive calcium may also be important. Preexisting renal insufficiency has been implicated in the pathogenesis of MAS, as have medications that affect renal calcium excretion, such as thiazide diuretics.

Thiazide Diuretics and Hypercalcemia

Chronic administration of thiazide diuretics may lead to hypercalcemia in patients treated with large doses of vitamin D (hypoparathyroid patients and patients with osteoporosis) and in patients with hyperparathyroidism. The mechanism of action may involve (1) reduced urinary excretion of calcium due to a direct tubular effect or extracellular fluid depletion with a secondary increase in tubular reabsorption of sodium and calcium or both; and (2) increased bone responsiveness to the resorptive actions of vitamin D and PTH.

Lithium and Theophylline Toxicity

Patients treated chronically with lithium may develop hypercalcemia with elevated PTH levels. The incidence of primary hyperparathyroidism in patients with bipolar affective disorders treated with lithium is 47-fold higher than in the general population. To date, 50 cases of parathyroid adenomas and hyperplasia associated with chronic lithium therapy have been reported.^{55,56} Theophylline toxicity may be associated with hypercalcemia, probably due to the stimulation of the beta-adrenergic receptors in bone.

Clinical Manifestations of Hypercalcemia

The symptoms of hypercalcemia depend on the rate of onset, magnitude, duration, underlying disorder, and comorbid conditions. Acute hypercalcemia may induce acute renal failure due to extracellular volume contraction and direct renal vasoconstriction. This abnormality is reversible, whereas chronic hypercalcemia may cause nephrolithiasis and nephrocalcinosis with tubulointerstitial scarring and chronic renal failure. Hypercalcemia may cause constipation, nausea and vomiting, and peptic ulcer disease. Polyuria is caused both by its natriuretic effect and impaired urinary concentration with features of nephrogenic diabetes insipidus.

Hypercalcemia leads to membrane hyperpolarization with a shortened QT interval, but cardiac arrhythmias are rare.

Neuromuscular effects of hypercalcemia include impaired concentration and memory, muscle weakness and fatigue, confusion, lethargy, stupor, and coma (Table 106-1).

Bone pain can occur in patients with hyperparathyroidism or malignancy. Osteoporosis of the cortical bone is associated with hyperparathyroidism. Familial hypocalciuric hypercalcemia is rarely associated with bone disease, but chondrocalcinosis and pseudogout have been reported to occur at high frequency.

Hypercalcemic crisis is a life-threatening emergency that warrants aggressive treatment. It may be a complication of primary hyperparathyroidism, malignancy, and other hypercalcemic disorders. It is characterized by very high serum calcium levels exceeding 15 mg/dL. The treatment is aimed at restoring the extracellular volume to normal and lowering the serum calcium levels. Acute hemodialysis with calcium-free dialysate may become a necessity.

Treatment of Hypercalcemia

Lowering of serum calcium concentration can be produced by: (1) inhibiting calcium release from the bone, increasing its deposition in the bone and other tissues, or both; (2) increasing the removal of calcium from the extracellular fluid or inhibiting its absorption in the bowel; and (3) decreasing the ionized fraction by complex formation with chelating substances.

Hypercalcemia augments urinary losses of sodium and water, resulting in the contraction of extracellular volume and reduced glomerular filtration rate. The latter leads to diminished urinary excretion of calcium and further aggravation of hypercalcemia. Therefore, the first therapeutic goal is to restore the extracellular volume to normal by IV administration of normal saline, which usually requires 3 to 4 liters of saline. This therapeutic action lowers the serum calcium concentration, partly by the dilutional effect and partly by the increased urinary excretion of calcium. There is a risk of extracellular volume overload during rapid IV administration of saline, which is particularly hazardous in elderly patients. Therefore, monitoring of the central venous pressure in this situation may be very helpful. Likewise, the addition of loop diuretics as an adjunct therapy may minimize the risk of fluid overload and increase the urinary excretion of calcium. The effect of loop diuretics as calciuretic agents requires prompt replacement of the urinary losses of sodium and water. The use of loop diuretics may be particularly beneficial in patients who develop hypercalcemia as a result of excessive secretion and high serum levels of PTH, PTHrP, or both. Hormone-induced, excessive tubular reabsorption of calcium plays a major role in the development and maintenance of hypercalcemia in these circumstances.

Bisphosphonates. Bisphosphonates (formerly diphosphonates) represent a group of drugs with a high therapeutic potential for the treatment of hypercalcemia in general and that are associated with malignancy in particular. Bisphosphonates have a great affinity for bone and bind tightly to calcified bone matrix, impairing both the mineralization and resorption of bone. In addition, they interfere with the function of osteoclasts and appear to have several direct effects on osteoclast function, including the prevention of osteoclast attachment to the bone matrix and the prevention of osteoclast differentiation and recruitment. Bisphosphonates are very potent inhibitors of bone resorption.

Ethane hydroxybisphosphonate (etidronate [Didronel]), is available for clinical use, but its potency as an antihypercalcemic agent is limited, at least when given orally. Reduction of the serum calcium concentration has been more successfully achieved with the second generation of bisphosphonates, including dichloromethylene bisphosphonate (clodronate) and amino-hydroxypropylidene bisphosphonate (pamidronate; ADP), which cause a reduction in bone resorption with a dose that has a negligible effect on bone mineralization. Pamidronate and etidronate are approved for the treatment of hypercalcemia of malignancy in the United States. Pamidronate is most effective when given via the IV route, with doses of 60 to 90 mg generally recommended. When compared, the effect of 30 mg of pamidronate is equal to that of 600 mg of clodronate and 1500 mg of etidronate in controlling hypercalcemia. In preliminary studies, the third generation of bisphosphonates, including alendronate, risedronate, and tiludronate, was found to be 500 times more efficient in inhibiting bone resorption than clodronate. Zoledronic acid is one of a new generation of nitrogen-containing bisphosphonates that has been found to be superior to pamidronate in clinical studies. This agent has been approved for clinical use.

Glucocorticoids. Glucocorticoids are effective at lowering serum calcium in states of vitamin D intoxication; possible mechanisms are the suppression of bone resorption and the reduction of intestinal absorption. Glucocorticoids are more effective in hypercalcemia associated with lymphoma, leukemia, and multiple myeloma than with other neoplasms. This effect might be related to a tumor lytic effect, interference with the production of osteoclast-activating cytokines, or both. The fall in serum calcium concentration occurs 1 to 2 days after starting the therapy.

Calcitonin. Calcitonin lowers serum calcium concentrations by inhibiting bone resorption and increasing urinary calcium excretion. The administration of calcitonin is associated with negligible toxicity; however, its therapeutic action has a limited duration because of the osteoclast escape phenomenon, which is apparent several days after starting therapy. The addition of glucocorticoids may be helpful to maintain efficacy.

Mithramycin (Plicamycin). Mithramycin is a cytotoxic substance derived from an actinomycete of the genus *Streptomyces* and is used mainly in the treatment of testicular tumors. Mithramycin lowers serum calcium concentrations by suppressing bone resorption and is available commercially as Mithracin. Its effect starts 24 to 48 hours after injection and lasts several days. Side effects include the suppression of bone marrow activity and hepatocellular and renal toxicity, which usually occurs with repeated doses.

Phosphate. Oral and IV salts of phosphorus lower the serum concentration and reduce the urinary excretion of calcium. This effect has been variously attributed to: (1) the deposition of mineral in the bone, (2) increased deposition of calcium in soft tissues, and (3) the suppression of bone resorption. The major untoward side effects of this therapy are extraskeletal calcifications, including nephrocalcinosis with resulting renal failure. Thus, the use of phosphates to treat hypercalcemia should be discouraged in patients with high serum phosphate and renal insufficiency. Phosphates may be given via the IV route at a dose of 20 to 30 mg of elemental phosphorus per kilogram of body weight over 12 to 16 hours. Serum calcium concentration should be determined at frequent intervals. The commercially available preparation for IV use is InPhos; 40 mL of this solution contains 1000 mg of phosphorus, 65 mEq of sodium, and 8 mEq of potassium.

Other Therapies. Gallium nitrate has been approved by the Food and Drug Administration for the treatment of hypercalcemia. It inhibits bone resorption by reducing the solubility of hydroxyapatite crystals. Nephrotoxicity is a major side effect of gallium nitrate. The use of a somatostatin congener (lanreotide) has been reported to successfully inhibit hypercalcemia in a patient with a PTHrP-secreting pancreatic neoplasm. The calcium-lowering effect is associated with the suppression of the serum levels of PTHrP.

The hypercalcemia associated with thyrotoxicosis and theophylline toxicity has been successfully treated with IV propranolol.

Intestinal absorption of calcium may be reduced by dietary restrictions and the binding of calcium in the bowel with cellulose phosphate and sodium phytate. Calcium also may be removed directly from the extracellular fluid with hemodialysis or peritoneal dialysis by employing calcium-free dialysate solution.

The reduction of serum-ionized calcium may be accomplished with IV Na-ethylene diamine tetraacetic acid (EDTA), which is a chelating agent. The complexed calcium is then excreted in the urine. The main disadvantage of this therapy is the nephrotoxicity of EDTA.

DISORDERS OF MAGNESIUM METABOLISM

Magnesium is the second most abundant intracellular cation. The intracellular concentration of magnesium ranges between 10 and 20 mEq/L; however, most of it is bound to organic compounds, including adenosine triphosphate (ATP). Of the fraction found in the extracellular space, one-third is bound to serum albumin. Therefore, the plasma levels of magnesium may be a poor indicator of the total body stores in the presence of hypoalbuminemia. The exchange between the extracellular and intracellular compartments appears to be slow, and changes in intake and intestinal absorption are tightly balanced by parallel changes in urinary excretion.^{57,58}

In the presence of normal kidney function, the serum levels of magnesium are maintained at nearly constant values ranging from 1.4 to 1.7 mEq/L (1.7–2.1 mg/dL). Hypermagnesemia can be encountered primarily with impaired kidney function and excessive oral or parenteral load. Hypomagnesemia results from decreased dietary intake, intestinal malabsorption, or renal losses.⁵⁷

Magnesium plays an important role in the function of many key enzymes including ATP. Intracellular magnesium is key to protein synthesis, oxidative phosphorylation, nucleic acid stability, the storing and utilization of energy, and enzymatic reactions. Extracellular magnesium is essential for nerve conduction, neuromuscular transmission, cardiac conduction and contractility, and vascular tone.

Although the total serum magnesium concentration is commonly utilized to assess magnesium, it is not ideal.⁵⁹ Changes in serum protein concentrations may affect the total serum concentration but are not reflective of total body magnesium. A magnesium tolerance test can be used to determine magnesium status but requires calculating the amount of retained parenteral magnesium. Measurement of ionized magnesium is not yet readily available.

Hypomagnesemia and Magnesium Depletion

Hypomagnesemia is a common problem in hospitalized patients, particularly in the ICU. The kidney is primarily responsible for magnesium homeostasis through regulation by calcium/magnesium receptors on renal tubular cells that sense serum magnesium levels.⁶⁰ Hypomagnesemia results from a variety of etiologies, ranging from poor intake, increased renal excretion, gastrointestinal (GI) losses, malabsorption, and a variety of endocrine dysfunctions. The causes of hypomagnesemia can be divided into two major categories: (1) extrarenal magnesium losses, including deficient intake, and (2) renal losses.

Extrarenal Losses of Magnesium

Dietary deprivation, prolonged malnutrition, tube feeding, and parenteral nutrition deficient in magnesium may induce cumulative

magnesium depletion and hypomagnesemia. GI losses may be caused by steatorrhea, severe diarrhea, or acute pancreatitis. Hypomagnesemia may also follow surgery for morbid obesity with short bowel syndrome and diarrhea.⁵⁷

Endocrine causes for hypomagnesemia include hyperthyroidism, hypercalcemia associated with malignancy, and hyperaldosteronism.⁶¹ Hungry bone syndrome after parathyroidectomy may lead to both hypocalcemia and hypomagnesemia owing to increased deposition of both divalent ions in the newly deposited bone mineral.

Chronic alcoholism is one of the leading causes of magnesium depletion. Poor nutrition, diarrhea, chronic pancreatitis, and renal tubular defects may contribute to hypomagnesemia.⁶² Severe burns may lead to sequestration of magnesium in necrotic tissue, including necrotic fat, leading to magnesium depletion. Acute dialysis for severe refractory hypercalcemia without the addition of magnesium to the dialysate may cause hypomagnesemia.

Renal Losses of Magnesium

Osmotic diuresis induced by salt loads, diabetic ketoacidosis, and mannitol all increase urinary excretion of many electrolytes, including magnesium. During recovery from ketoacidosis, especially after phosphate replacement, a precipitous fall in serum magnesium may occur.

Hypercalcemia as seen with primary hyperparathyroidism, hyperthyroidism, and IV administration of calcium causes renal losses of magnesium. Similarly, loop diuretics cause renal magnesium and calcium wasting, whereas thiazides enhance urinary excretion of magnesium but cause tubular retention of calcium. Primary hyperaldosteronism and the syndrome of inappropriate antidiuretic hormone are associated with modest increases in urinary magnesium excretion.

Renal magnesium wasting has been observed in patients treated with aminoglycosides, amphotericin B, and cisplatin.⁶³⁻⁶⁵ These agents may lead to potassium wasting and renal tubular acidosis. Cyclosporine and tacrolimus cause magnesium wasting with potassium retention. Loop diuretics can also lead to magnesium wasting. The diuretic phase of acute renal failure also may lead to magnesium loss.

Inherited Disorders of Renal Magnesium Losses

Isolated Dominant Hypomagnesemia. These patients present with generalized seizures in childhood. Hypocalciuria, but not hypocalcemia, is present.

Isolated Recessive Hypomagnesemia. Affected individuals present with symptoms of hypomagnesemia during infancy. Hypomagnesemia due to increased urinary magnesium excretion is the only biochemical abnormality. Linkage analysis has thus far excluded all established gene loci.⁶³

Familial Hypomagnesemia with Hypercalciuria and Nephrocalcinosis (FHHNC). FHHNC is an autosomal recessive disorder characterized by renal magnesium and calcium wasting, bilateral nephrocalcinosis, and nephrolithiasis with progressive renal failure. FHHNC patients present during early childhood with recurrent urinary tract infections, polyuria and polydipsia, failure to thrive, abdominal pain, vomiting, tetanic episodes, and generalized seizures. PTH levels are increased before renal failure.

Autosomal Dominant Hypocalcemia. Activating mutations of the calcium-sensing receptor lead to hypocalcemia, hypocalciuria, and in about 50% of patients, hypomagnesemia.

Classic Bartter Syndrome. Classic Bartter syndrome is caused by mutations in the *CLCNKB* gene encoding the basolaterally located renal chloride channel CIC-KB, which mediates chloride efflux from the tubular epithelial cells to the interstitium. Hypomagnesemia is detected in up to 50% of patients with mutations in *CLCNKB* in chromosome 1p36.⁶³

Gitelman Syndrome. Gitelman syndrome is an autosomal recessive disorder. Symptoms include muscle weakness and tetanic episodes that are related to profound hypomagnesemia. Patients always present with hypocalciuria; the presence of both hypomagnesemia and hypocalciuria is diagnostic. Loss-of-function mutations in the gene coding for the NaCl cotransporter of the distal convoluted tubule is the underlying abnormality.

TABLE 106-1

Clinical Manifestations of Abnormalities in Magnesium and Calcium

| INCREASED SERUM LEVELS | | |
|------------------------|--|---|
| SYSTEM | MAGNESIUM | CALCIUM |
| Gastrointestinal | Nausea/vomiting | Anorexia, nausea/vomiting, abdominal pain, constipation |
| Neuromuscular | Weakness, lethargy, ↓ reflexes | Depression, confusion, coma, muscle weakness, back and extremity pain |
| Cardiovascular | Hypotension, cardiac arrest | Hypotension, arrhythmias |
| Renal | — | Polydipsia, polyuria |
| DECREASED SERUM LEVELS | | |
| SYSTEM | MAGNESIUM | CALCIUM |
| Gastrointestinal | — | — |
| Neuromuscular | Hyperactive reflexes, muscle tremors, tetany, delirium, seizures | Hyperactive reflexes, paresthesias, weakness, paralysis, tetany, seizures, carpal spasm |
| Cardiovascular | Arrhythmia | Heart failure |

Clinical Consequences of Magnesium Depletion

The clinical manifestations of hypomagnesemia depend on its severity, duration, and coexistent electrolyte abnormalities. Hypomagnesemia and the depletion of intracellular magnesium stores, especially in the cardiac muscle, have been considered to underlie cardiovascular and other functional abnormalities, including cardiac arrhythmias such as atrial fibrillation and torsades de pointes, impairment of cardiac contractility, and vasoconstriction. This may be especially important in patients undergoing coronary artery bypass graft surgery.⁶⁶ Magnesium depletion is also characterized by neuromuscular and central nervous system hyperactivity, and the symptoms are similar to those of calcium deficiency, including hyperactive reflexes, muscle tremors, and tetany with a positive Chvostek's sign (see Table 106-1). Severe deficiencies in magnesium can lead to delirium and seizures. The neurologic effects of magnesium balance were recently demonstrated in a prospective observational study that demonstrated an association between high dietary magnesium intake and reduced stroke rate.⁶⁷

Hypomagnesemia is important not only for its direct effects on the nervous system but also because it can produce hypocalcemia and lead to persistent hypokalemia. When hypokalemia or hypocalcemia coexists with hypomagnesemia, magnesium should be aggressively replaced to assist in restoring the potassium or calcium homeostasis. Prolonged insufficiency of magnesium results in anorexia, nausea, vomiting, and weakness within weeks and in paresthesias and muscle weakness, cerebral seizures, and cardiac manifestations within months.

ECG changes in magnesium depletion include widening of the QRS complex and peaking of T waves, followed by prolongation of the PR interval and diminution of T waves. Ventricular arrhythmias are more common during myocardial ischemia after cardiopulmonary bypass. Magnesium prevents the increase in action potential duration and prolongation in membrane repolarization, which normally occurs in ischemic myocardium.⁶⁶

Treatment of Hypomagnesemia

The amount and route of magnesium replacement depend on the degree of hypomagnesemia and severity of the symptoms. In patients with asymptomatic hypomagnesemia, treatment of the underlying disorder (e.g., diarrhea) and dietary adjustments may solve the problem.

Correction can be oral if the hypomagnesemia is asymptomatic and mild. Oral magnesium can lead to diarrhea, which may limit its utility. Magnesium oxide tablets have high magnesium content compared with other oral preparations such as magnesium chloride, magnesium sulfate, and magnesium acetate. Oral replacement of magnesium can also be made with antacids that contain both magnesium and aluminum in patients who develop diarrhea from magnesium oxide. If hypomagnesemia is associated with the use of diuretics that need to be continued, the addition of potassium-sparing diuretics such as amiloride may be helpful. Amiloride may also be considered in other states of magnesium wasting such as Bartter or Gitelman syndrome.

The use of IV magnesium repletion depends on the severity and symptoms associated with hypomagnesemia. For patients with severe deficits (<1.0 mEq/L) or those who are symptomatic, administer 1 to 2 g of magnesium sulfate IV over 15 minutes. Caution should be exercised when giving large amounts of magnesium, as magnesium toxicity may develop. Administration of simultaneous calcium gluconate counteracts the adverse side effects of rapidly rising magnesium levels and corrects hypocalcemia, which is frequently associated with hypomagnesemia.

In states of emergency such as torsades de pointes, 2 g of magnesium sulfate over 2 minutes is recommended to suppress early depolarization. Magnesium is also a first-line drug for use in eclampsia.⁶⁸ Magnesium has a potentially deleterious effect on arteriovenous conduction; therefore, it is relatively contraindicated in greater than first-degree arteriovenous block and sinus bradycardia.

Hypermagnesemia

Normal kidneys can dispose of large filtered loads of magnesium by attenuating tubular reabsorption to a minimum after the renal tubular T_m is exceeded. Thus, intact kidneys are the major regulating organ for maintaining magnesium balance. The most common cause of hypermagnesemia is the concurrence of excessive magnesium load in the presence of impaired renal function. Often, a large magnesium load is the consequence of therapeutic employment of magnesium salts as laxatives or enemas. Hypermagnesemia may be more common in the elderly, who often consume magnesium salts as antacids and laxatives and display aging-related reduction in renal function.

Endogenous magnesium loads may be released in rhabdomyolysis from necrotic muscles and in tumor lysis from malignant cells

destroyed by chemotherapy. Acute IV magnesium loads, such as those given in preeclampsia, may cause transient hypermagnesemia occasionally accompanied by hypocalcemia as a result of the acute suppression of PTH by high serum magnesium. Children born to mothers with preeclampsia may have hypermagnesemia as well.

Patients with chronic renal failure may present with mild elevation of serum magnesium; however, the ingestion of magnesium salts should be avoided because they may induce life-threatening hypermagnesemia.

Adrenal insufficiency, primary hyperparathyroidism, MAS, and familial hypocalciuric hypercalcemia may be associated with hypermagnesemia. Lithium and theophylline have also been reported to cause hypermagnesemia.

Clinical Manifestations

Mild hypermagnesemia with serum magnesium levels less than 3 mEq/L (3.6 mg/dL, 1.5 mmol/L) is usually asymptomatic. Above these values, the severity of the symptoms parallels the magnitude of the elevation in serum magnesium. The major manifestations of hypermagnesemia are neuromuscular, central nervous system, and cardiovascular abnormalities (Table 106-1).

Neuromuscular manifestations relate to the curare-like action of hypermagnesemia, hindering the neuromuscular impulse transmission. Such neuromuscular abnormalities are first manifested as reduced deep tendon reflexes progressing to areflexia, muscle paralysis, and apnea. Central nervous system abnormalities consist of lethargy and coma.

The cardiovascular effects of hypermagnesemia may be related to its activity as an ion channel blocker. These effects lead to bradycardia and hypotension and may progress to cardiac arrest. ECG abnormalities are similar to those seen with hyperkalemia and consist of an increased PR interval, widened QRS, and peaked T waves. With a rise in serum magnesium above 10 mEq/L, complete heart block and cardiac arrest are the terminal events.

Treatment of Hypermagnesemia

Treatment for hypermagnesemia consists of measures to withhold exogenous sources of magnesium, correct volume deficit, and correct acidosis if present. To manage acute symptoms, calcium chloride (5–10 mL) should be administered to antagonize the cardiovascular effects. If elevated levels or symptoms persist, dialysis is indicated.

KEY POINTS

Hypocalcemia

1. Serum levels of 25(OH) vitamin D serve as an estimate of the body stores of vitamin D. Low serum concentrations of 25(OH) vitamin D indicate a state of vitamin D deficiency.
2. Hypoparathyroidism is a common cause of hypocalcemia. Magnesium depletion inhibits parathyroid hormone (PTH) secretion and peripheral responses to PTH and to vitamin D; it also blunts the calcemic effect of intravenous calcium. Thiazides enhance the calcemic effect of vitamin D, whereas furosemide aggravates the hypocalcemia.
3. Neuromuscular manifestations of hypocalcemia include confusion or coma, focal and generalized seizures, and respiratory arrest. Cardiovascular complications of acute hypocalcemia include hypotension, bradycardia, and ventricular arrhythmias such as torsades de pointes.
4. Hypoparathyroidism, and particularly, the variant autosomal dominant hypocalcemia, should be treated cautiously. Raising

serum calcium levels may cause hypercalciuria, with increased risk of nephrocalcinosis and renal failure.

Hypercalcemia

1. Malignancy is the prevalent cause of hypercalcemia, accounting for 70% to 80% of all cases, and is most commonly seen in hospitalized patients. Primary hyperparathyroidism is common in the outpatient setting, accounting for 10% to 20% of all cases of hypercalcemia. Milk-alkali syndrome ranks third.
2. Familial hypocalciuric hypercalcemia is a form of parathyroid hyperplasia with autosomal dominant transmission. It is caused by an inactivating mutation of a calcium-sensing receptor. The clinical course is benign, without nephrolithiasis, but hypermagnesemia, pancreatitis, and chondrocalcinosis may occur.
3. Hypercalcemic crisis is a life-threatening emergency. It may be a complication of primary hyperparathyroidism, malignancy, and

Continued

KEY POINTS—cont'd

other hypercalcemic disorders. It warrants aggressive treatment to lower the serum calcium concentration.

4. The first goal in treating hypercalcemia is to restore the extracellular volume to normal by intravenous administration of normal saline.

Hypomagnesemia

1. Hypomagnesemia is common in hospitalized patients (>10%) and even more so in the intensive care unit setting (>50%). Concerns regarding hypomagnesemia are focused on its potential role in cardiac arrhythmias (e.g., torsades de pointes) and sudden death.
2. Hypomagnesemia leads to renal losses of potassium, and vice versa, hypokalemia augments urinary losses of magnesium. In the former, hypokalemia may be refractory to potassium replacement unless magnesium repletion is accomplished first.

Hypermagnesemia

1. The most common cause of hypermagnesemia is excessive magnesium loads in the presence of impaired renal function. Very often, a large magnesium load comes from the therapeutic use of magnesium salts as laxatives or enemas.
2. Neuromuscular manifestations of hypermagnesemia relate to its curare-like effect, leading to the loss of reflexes, muscle weakness and paralysis, and apnea. Central nervous system abnormalities are lethargy, drowsiness, dilated pupils, and coma.
3. The cardiovascular effects of hypermagnesemia consist of bradycardia and hypotension. The electrocardiogram shows an increased PR interval and QRS complex. Complete heart block and cardiac arrest are the terminal events.

ANNOTATED REFERENCES

Awad SS, Miskulin J, Thompson N. Hyperparathyroidism in patients with prolonged lithium therapy. *World J Surg* 2003;27:486-8.

This report calls attention to the association of chronic lithium therapy for bipolar disorders with the development of hypercalcemia with elevated parathyroid hormone levels. The incidence of primary hyperparathyroidism in patients treated with lithium is 47-fold higher than in the general population. The most common cause of primary hyperparathyroidism is parathyroid adenoma.

Information from NIH Conference. Diagnosis and management of asymptomatic primary hyperparathyroidism: Consensus Development Conference statement. *Ann Intern Med* 1991;114:593-7.

This landmark article summarizes the diagnosis and management of asymptomatic primary hyperparathyroidism, specifically the indications for surgical therapy, from the National Institutes of Health Consensus Development Conference Panel composed of endocrinologists, surgeons, radiologists, epidemiologists, and primary health providers.

Zivin JR, Gooley T, Zager RA, et al. Hypocalcemia: a pervasive metabolic abnormality in the critically ill. *Am J Kidney Dis* 2001;37:689-98.

This article presents an interesting finding that hypocalcemia was present in 88% of critically ill patients who were admitted to intensive care units. The level of hypocalcemia correlated with the severity of the disease. The mechanism of this abnormality is unknown.

Konrad M, Weber S. Recent advances in molecular genetics of hereditary magnesium-losing disorders. *J Am Soc Nephrol* 2003;15:249-60.

This is a comprehensive, in-depth review of recently unfolding information on abnormalities associated both with intestinal and renal causes of magnesium wasting. The paper focuses on the molecular aspects of hereditary genetically transmitted defects in tubular epithelial and intestinal magnesium transport causing hypomagnesemia.

The goals of fluid administration are to optimize tissue oxygenation by augmenting intravascular volume, improving left ventricular preload, and increasing cardiac output.¹ This chapter reviews the timing and considerations for choice of therapy in volume repletion, as well as the effects of fluid volume overload in the postresuscitation period.

TIMING OF INITIAL VOLUME THERAPY

Studies from the early 2000s suggested that earlier recognition and treatment of septic shock correlated with improved outcomes. In a report by Rivers et al., the Early Goal-Directed Therapy Collaborative Group randomized subjects to receive either intensive treatment for septic shock within the initial 6 hours of therapy versus standard therapy provided in the emergency department.² Standard and early goal-directed therapy (EGDT) groups received antibiotics, vasoactive medications, and intravenous (IV) fluid for volume resuscitation. Goals for fluid administration included infusion of crystalloid in 500-mL boluses every 30 minutes in order to achieve a central venous pressure of 8–12 mm Hg as a marker of effective repletion of intravascular volume and response to fluids. Whereas the total volume of fluid administered by 72 hours was equivalent, the EGDT group received substantially more IV fluid in the first 0–6 hours of treatment. Compared with the standard therapy group, significant improvements related to in-hospital mortality were observed in the group assigned to earlier administration of volume-based resuscitation in conjunction with other therapies, including the optimization of central venous oxygen saturation with red cell transfusions and the use of inotropes, if necessary. In-hospital mortality was 30.5% in the EGDT group, compared with 46.5% in the standard therapy group ($P = 0.009$). Replication of results in other studies prompted guidelines for the treatment of sepsis to include early volume repletion as part of protocol-based, quantitative resuscitation to reverse tissue hypoperfusion.^{3,4} In the Surviving Sepsis Campaign, initial resuscitation recommendations for the first 6 hours included treatment aimed at maintaining a central venous pressure of 8–12 mmHg, a mean arterial pressure more than or equal to 65 mm Hg, urine output more than or equal to 0.5 mL/kg/h, and mixed venous oxygen saturation greater than 65%.⁵

Meeting hemodynamic stabilization endpoints in such a manner with goal-directed therapy and other supportive measures remains desirable in most cases, especially in patients who prove to be responsive to fluid. However, more recent multicenter studies re-examining this topic have not replicated survival benefits, and the advantages of EGDT have been questioned. The Australasian Resuscitation in Sepsis Evaluation (ARISE) study examined EGDT resuscitation in patients with septic shock.⁶ Sixteen hundred patients were randomized to EGDT or usual care. On average, patients in the EGDT group received larger volumes of IV fluid in the first 6 hours than the usual care group. Those in the EGDT group were also more likely to receive red blood cell transfusions. At 90 days, however, no significant differences were observed in patient survival. In-hospital mortality, the duration of organ support, and the length of hospital stay were also similar. The Protocol-based Care for Early Septic Shock (ProCESS) investigative group showed comparable results, with no benefits found with EGDT.⁷ ProCESS was a multicenter trial that randomized 1341 patients with septic shock to receive protocol-based EGDT, protocol-based standard

therapy, or usual care for 6 hours of resuscitation. The investigators did not require placement of central venous catheters, administration of inotropes, or blood transfusions in the protocol-based standard therapy group, as compared with the use of these therapies in the EGDT group. Overall, the total volume of fluid administered during the 6-hour study period was reported as being significantly different between the groups. Again, no differences in survival were observed at 90 days. There was also no significant impact on 1-year mortality, the duration of time spent on mechanical ventilation, or the duration of time on renal replacement therapy.

TYPE OF VOLUME THERAPY

When deciding on IV fluid therapy, the choices can be broadly classified into three major categories. Crystalloid fluids have long been considered the mainstay of volume replacement in the hospital setting and include normal saline (NS), lactated Ringer's (LR) solution, Hartmann's solution, and other balanced salt solutions such as Plasma-Lyte. A second broad category includes colloid preparations such as albumin, hydroxyethyl starch (HES), dextran, and gelatin. Finally, blood products, including packed red blood cells, can be used for volume repletion in the treatment of hypoperfusion due to inadequate circulating volumes. Table 107-1 compares the osmolality and composition of human plasma and common isotonic crystalloid fluid preparations.

Crystalloids Versus Colloids

For years, the choice between crystalloids and colloids as therapeutic fluids in the intensive care unit (ICU) has been a topic of debate and investigation. In an analysis of multiple population studies, Goldwasser and Feldman observed that mortality was inversely associated with serum albumin levels.⁸ For each 2.5-g/L decrement in the serum albumin concentration, a correlative 24% to 56% increase in the risk of death was detected. This relationship held true in healthy populations as well as in those who suffered from acute and chronic illnesses. Several mechanisms for the protective effects of the albumin molecule have been explored. Among these, infused albumin reportedly has free radical scavenging antioxidant properties that may have clinical importance.⁹ Moreover, the proposed advantages for prescribing colloid over crystalloid fluid in resuscitation strategies for critically ill patients include concepts based on hemodynamic Starling's principles and the role of plasma oncotic pressure. Theoretically, large colloid molecules that persist in the circulation enhance water reabsorption from the interstitial space and maintain the volume within the vasculature for longer periods.¹⁰ Ideally, this characteristic would reduce the large fluid volumes that are often required for resuscitation and improve clinical outcomes.¹¹

Despite the potential benefits for albumin and colloids in lieu of crystalloid solutions in volume repletion strategies, prospective and randomized controlled studies undertaken to prove these advantages have yielded variable results. For example, investigations have demonstrated benefit with albumin administration and support its clinical safety. In one such study, a group of 100 patients with hypoalbuminemia in the ICU were randomized to receive (versus not receive) albumin as part of their treatment regimen.¹² The groups were well matched and had similar baseline serum albumin concentrations and

Acute Physiology and Chronic Health Evaluation II (APACHE II) scores. Significant improvements in Sequential Organ Failure Assessment (SOFA) scores were observed in the albumin-treated group. Interestingly, significant decreases in fluid gains were also seen in the albumin-treated group. These results led the investigators to suggest that albumin administration may improve organ function in critically ill patients with hypoalbuminemia. The Saline versus Albumin Fluid Evaluation (SAFE) study was a large trial that included nearly 7000 ICU patients with trauma, acute respiratory distress syndrome (ARDS), and severe sepsis.¹³ The participants were randomized to receive either 4% albumin or NS for intravascular fluid resuscitation. In a subgroup analysis of patients with severe sepsis, those in the albumin-treated group had a significantly lower heart rate and a significantly higher central venous pressure on days 1-3.¹⁴ No between-group differences were detected in the total SOFA score, and similar numbers of patients required renal replacement therapy in the saline- and albumin-treated groups. Multivariate logistic regression analysis revealed that the adjusted odds ratio for death in the albumin-treated versus saline-treated group was 0.71 (85% confidence interval [CI]: 0.52-0.97; $P = 0.03$), suggesting that albumin treatment may decrease the risk of death in severe sepsis. Furthermore, data from a meta-analysis suggested that albumin administration is safe. In 55 trials that evaluated many different types of patients including those with trauma, burns, hypoalbuminemia, and ascites, albumin administration did not adversely affect mortality.¹⁵

In contrast to the studies suggesting benefit with albumin therapy in sepsis, other large prospective randomized trials have failed to support a clear benefit of infusing albumin over crystalloid solutions in patients in the ICU setting. In the larger and more diverse group of original SAFE study participants discussed above, investigators found no between-group differences in death or new episodes of single- or multiorgan system failure between those treated with albumin versus saline.¹³ There was also no significant difference in the number of days spent in the ICU, length of hospital stay, or days of renal replacement therapy in the subgroup analyses. Similarly, the Colloids Versus Crystalloids for the Resuscitation of the Critically Ill (CRISTAL) trial tested colloids compared with crystalloids for fluid resuscitation in critically ill patients with shock from sepsis, trauma, or hypovolemia without sepsis.¹⁶ In addition to 4% and 20% albumin, the colloid arm of CRISTAL included gelatins, dextrans, and HES. At 28 days after study enrollment, even though colloid resuscitation was associated with fewer days of mechanical ventilation and more days without vasopressor therapy, no significant differences in mortality were observed between the patients who received colloids and those who received

crystalloids. Patients with severe sepsis have also been randomized to receive crystalloid plus albumin therapy compared with crystalloids alone. In the more than 1800 randomized patients in the Albumin Italian Outcome Sepsis (ALBIOS) study, significantly higher mean arterial pressures and lower net fluid gains were observed in the albumin plus crystalloid therapy group.¹⁷ However, the investigators also noted that the total daily amount of fluids administered did not differ between the groups and, more importantly, there were no significant differences in patient survival at 28 or 90 days between the groups. The Cochrane analysis of pooled data on this topic also found no evidence that colloids reduced the risk of death compared with crystalloids in the treatment of critically ill patients.¹⁸ Overall, there remains a paucity of data to suggest that clear benefits exist for administering albumin or other colloid solutions instead of crystalloids in critically ill patients requiring volume repletion. The lack of resounding benefit is compounded by the high cost of albumin, which also makes it less attractive for routine use.¹⁸

There is opposing evidence that suggests that colloid solutions such as albumin may be associated with harmful effects. Though they tended to have higher critical illness severity scores, patients in the Sepsis Occurrence in Acutely ill Patients (SOAP) study who received albumin at any time during their ICU stay had a higher risk of death.¹⁹ A systematic review of 37 randomized trials comparing crystalloid to colloid administration also hinted at safety concerns. The investigators found that colloid resuscitation was associated with a 4% increase in the absolute risk of mortality (95% CI, 1.00-1.08) and concluded that the difference in the effect of the colloids was not due to the types of inciting injuries.²⁰

The harm associated with colloid infusion may be more pronounced with respect to specific organ systems or types of colloids. In a post-hoc analysis of the SAFE study, albumin administration in patients with traumatic brain injury was associated with higher mortality compared with those who received crystalloids.²¹

Hydroxyethyl Starch

Convincing evidence for harm was reported for critically ill patients treated with the synthetically derived HES. Of 7000 randomized patients in the Crystalloid versus Hydroxyethyl Starch Trial (CHEST), there was no significant mortality difference in those resuscitated with NS versus HES.²² There was, however, a significant difference in the adverse outcomes. Renal replacement therapy was required in 235 of 3352 patients (7.0%) in the HES group versus 196 of 3375 (5.8%) in the NS group (relative risk, 1.21; 95% CI, 1.00-1.45; $P = 0.04$). In the

HES- and saline-treated patient groups, renal injury occurred in 34.6% and 38.0% ($P = 0.005$) and renal failure occurred in 10.4% and 9.2% ($P = 0.12$), respectively. Overall, HES was associated with significantly more adverse events (5.3% vs. 2.8%, $P < 0.001$). Similarly, among patients with sepsis who were randomized to receive IV fluid resuscitation with HES versus Ringer's acetate, the risk of death at 90 days was higher in those who received HES.²³ In that study, patients with sepsis who were treated with HES were also more likely to require renal replacement therapy. These findings were confirmed in meta-analyses from more than 35 trials in which HES was associated with a significantly increased risk of mortality and acute kidney injury (AKI).²⁴ Mechanistically, the total mass of the HES molecule has been proposed as being directly toxic to renal proximal tubular cells, leading to the pathologic sequence of events that culminates in AKI.²⁵ This is contrary to other reports suggesting that it is the origin of the HES molecule (potato or corn), the carrier solution, or the effects of systemic inflammation that may be damaging to kidney cells.

Albumin Use in Select Clinical Settings

Just as there are clinical situations in which the infusion of albumin and colloid solutions may be harmful, there are also specific circumstances where these fluids could have important and beneficial roles in the treatment of critically ill patients. In a randomized, non-blinded clinical trial that examined 126 patients with cirrhosis and spontaneous bacterial peritonitis, participants were randomized to treatment with either IV antibiotics alone or IV antibiotics with albumin.²⁶ The dose of albumin administered was 1.5 g/kg at diagnosis, with another 1 g/kg infused on day 3. In the patients who received albumin as well as antibiotics, statistically significant reductions in renal impairment and death were observed. Additionally, a recent meta-analysis in 688 burn shock patients reported that treatments that included IV albumin were associated with statistically significant reductions in mortality, as well as in the occurrence of compartment syndrome.¹¹ The authors attempted to exclude what they felt were potentially biased studies from the meta-analysis. Although larger, prospective randomized trials are needed to guide management in burn shock resuscitation, these results suggest that albumin has the potential to improve outcomes.

In the majority of cases that require IV fluid volume resuscitation in the ICU, there does not seem to be a robust signal favoring infusion of albumin or other colloid therapies over crystalloid fluids as first-line treatment for hypovolemia and septic shock. Crystalloids remain the treatment of choice in most settings.

Chloride Restrictive and Balanced Crystalloid Strategies

Increasing evidence indicates that isotonic crystalloid fluid preparations are not uniform or equivalent with respect to their side-effect and physiologic profiles. Despite isotonicity, NS is hyperchloremic compared to plasma (Table 107-1). In animal studies, the effects of high chloride levels have been implicated in severe renal vasoconstriction, the suppression of plasma renin activity, and reduced glomerular filtration rate.²⁷⁻²⁹ In healthy human volunteers, magnetic resonance imaging studies have demonstrated that infusions of NS can cause significant reductions in renal blood flow velocity, as well as reductions in the perfusion of renal cortical tissue.³⁰

Organ hypoperfusion is common in critically ill patients, but lactic acid production alone is not sufficient to explain all the cases of metabolic acidosis in the ICU.³¹⁻³³ In addition to the aforementioned renal hemodynamic changes, IV fluids with superphysiologic concentrations of chloride, such as NS, have been associated with the development of hyperchloremic metabolic acidosis. McFarlane and Lee observed this phenomenon while studying surgical patients who were randomly assigned to receive either 0.9% NS or Plasma-Lyte 148 during major abdominal surgery.³⁴ Patients receiving NS had significantly higher serum chloride concentrations, lower

serum bicarbonate concentrations, and higher base deficit measurements compared with those who received Plasma-Lyte 148. Administration of NS has reproducibly been associated with decreases in serum bicarbonate levels or acidemic-range arterial pH values.^{30,35-37} Extracellular dilution of buffer caused by the infusion of large volumes of fluid that lack bicarbonate may explain some of these changes.³⁸ Another postulate employs the strong ion difference (SID) theory of acid-base evaluation to describe these effects. In the SID theory, acidosis can occur if the apparent difference between strong cations and anions in solution is reduced.³⁹ As such, hyperchloremia due to excessively larger gains in chloride (anion) concentration may contribute to the metabolic acidosis that has been observed with NS administration.⁴⁰⁻⁴³

In large-cohort observational studies, the deleterious physiologic effects of hyperchloremia and NS administration are reflected in clinical outcomes. In 22,851 surgical patients with normal preoperative kidney function and normal serum chloride concentrations, postoperative hyperchloremia was associated with higher 30-day mortality, longer hospital stays, and more postoperative kidney dysfunction.⁴⁴ A similar study in more than 30,000 adult patients undergoing major abdominal surgery found that those who received NS had more postoperative complications, including infection, renal failure requiring dialysis, and blood transfusions.⁴⁵ Among patients in the ICU with sepsis, a retrospective analysis of more than 50,000 patients showed that balanced fluid administration (e.g., LR) was associated with a significantly lower in-hospital mortality (19.6% vs. 22.8%; relative risk, 0.86; 95% CI, 0.78-0.94).⁴⁶ Similarly, among patients with systemic inflammatory response syndrome, in-hospital mortality was lower when the total chloride load was reduced.⁴⁷ Yunos et al. detected adverse events associated with chloride-liberal IV fluid administration in critically ill ICU patients.⁴⁸ These investigators conducted a prospective, open-label pilot study that examined patients in an academic ICU. Patients were treated with standard IV fluids during a 6-month control period, after which NS and other chloride-rich fluids were restricted to specialty-attending approval. The primary outcomes included a rise in serum creatinine concentration from baseline and incident AKI as defined by RIFLE (Risk, Injury, Failure, Loss, and End-stage kidney disease) classification. During the intervention period, saline administration decreased significantly. When the study periods were compared, those who received chloride-restrictive therapy had a lower mean rise in serum creatinine concentration while in the ICU and the incidence of AKI was significantly diminished. After adjustment for covariates, an increased risk of requiring renal replacement therapy was observed in the chloride-liberal cohort.

It has been more difficult to quantify the adverse effects of administering chloride-liberal crystalloids in prospective randomized clinical trials. Although these studies included predominantly perioperative and trauma patients, the results were less striking. When comparing resuscitation with 0.9% NS versus Plasma-Lyte A in 65 trauma patients, administration of Plasma-Lyte resulted in a lower frequency of hyperchloremia and was associated with greater correction of acid-base abnormalities.⁴⁹ However, investigators noted that there were no significant differences in cumulative urine output, measures of resource utilization, or mortality between those resuscitated with saline versus Plasma-Lyte at 24 hours. Similarly, a report in 60 patients undergoing abdominal aortic aneurysm repair revealed that intraoperative randomization to LR or NS (double-blinded) resulted in a higher frequency of acidosis requiring bicarbonate therapy in those receiving NS, but did not significantly impact the duration of mechanical ventilation, length of ICU stay, length of hospital stay, or postoperative complications.⁵⁰ In patients undergoing kidney transplantation, the use of NS versus balanced crystalloids has been associated with a higher incidence of metabolic acidosis; however, fluid type did not negatively impact kidney allograft function as determined by serum creatinine concentration on postoperative day 3.^{35,51}

Although we await large clinical trials directly comparing various crystalloid solutions in patients with sepsis and other common ICU conditions, based on the aforementioned evidence, there may be a

role for chloride-restrictive alternatives to NS in patients who have developed (or are at risk for developing) metabolic acidosis and/or renal insufficiency. Concerns with administering physiologically balanced solutions more closely matched to serum include the perceived risk of hyperkalemia due to their higher potassium concentrations. Even in clinical situations potentially associated with higher risk for hyperkalemia, evidence supports that these balanced solutions are generally safe with appropriate monitoring. For example, in a prospective randomized trial of patients with rhabdomyolysis, treatment with LR was not associated with significant differences in serum potassium concentration compared with treatment with NS.⁵² In patients with diabetic ketoacidosis, in which serum potassium levels can rise due to the combination of hyperosmolality, insulin deficiency, and AKI, patients who were resuscitated with balanced Plasma-Lyte instead of NS had faster resolution of acidosis and lower 6- and 12-hour serum potassium concentrations.⁵³ After kidney transplantation, patients who received NS had higher frequencies of hyperkalemia relative to those who received LR.³⁵

Blood Transfusions

In critically ill patients with severe blood loss and hemorrhagic shock, blood transfusions are appropriately considered a foundation of treatment. In patients suffering from sepsis and other acute illnesses, red blood cell transfusions have been used to enhance oxygen delivery to poorly perfused tissue as a supplement to other fluid resuscitation and vasopressor/inotropic support. Unfortunately, data sufficient to guide management and support the benefit of red blood cell transfusion in critically ill patients with sepsis have yet to emerge.

Observational studies have detected possible mortality benefits with red blood cell transfusions in critically ill patients with sepsis.^{54,55} Among the European ICUs that participated in the SOAP study, multivariate analysis of more than 3,000 patients revealed that blood transfusions were not associated with significantly higher mortality rates. In matched-pair propensity analysis, a higher 30-day survival rate was observed in the group that had a transfusion at any time while in the ICU ($P = 0.004$).⁵⁴ In contrast, other multicenter and randomized trials have not shown similar benefit. In 838 critically ill patients in the ICU that were randomized to receive either restrictive or liberal blood transfusion strategies when hemoglobin concentrations were less than 9.0 g/dL, the mortality rate during hospitalization was significantly lower when patients were randomized to the transfusion restrictive-strategy group (22.2% vs. 28.1%, $P = 0.05$).⁵⁶ In an examination of 45 observational cohort studies that combined data from 272,596 ICU, trauma, and surgical patients, red blood cell transfusions were associated with increased morbidity and mortality.⁵⁷ The pooled odds ratio for death generated from the results of 12 studies was 1.7 (95% CI, 1.4-1.9). Transfusions were also associated with infectious complications, risk for developing multiorgan dysfunction syndrome, and ARDS.

The Surviving Sepsis Guidelines include recommendations to provide blood transfusions in order to maintain hematocrits above 30% during the first 6 hours of resuscitation if there is evidence of tissue hypoperfusion after adequate repletion of the circulating volume. Guidelines for transfusion after the resolution of tissue hypoperfusion aim to keep the hemoglobin concentration between the targets of 7.0 g/dL and 9.0 g/dL in most patients.⁵ To examine these thresholds, Holst et al. randomized approximately 1000 patients with septic shock and hemoglobin concentrations ≤ 9 g/dL to receive red blood cell transfusions to hemoglobin thresholds of 7 g/dL or 9 g/dL.⁵⁸ Those who were randomized to the higher threshold received a median of 4 units of blood during the study period, whereas those in the lower threshold group received a median of 1 unit of blood. At 90 days, there was no significant difference in mortality between the groups. These results held true after adjusting for baseline risk factors. In addition, there was no significant difference in the number of ischemic events, severe reactions, or use of life support between the two groups. As such, the optimal hemoglobin target in patients with sepsis in the ICU remains uncertain.

EFFECTS OF VOLUME OVERLOAD

Volume therapy in critically ill patients aims to avoid and reverse the consequences of hypoperfusion and end organ damage. Due to the large volumes of IV fluid that are often required, deleterious effects from volume overload can develop during the management of shock. These effects may be manifested systemically, for example, by hypertension and increased myocardial demand, pulmonary congestion with respiratory failure, and/or peripheral edema.⁵⁹ Recent evidence supports that fluid resuscitation resulting in clinical volume overload is not beneficial to critically ill patients and negatively affects clinical outcomes. An early signal came from a retrospective study of patients who had sepsis.⁶⁰ Achieving a net negative fluid balance greater than or equal to 500 mL within the first three hospital days correlated with improved survival independent of age, critical illness, and kidney function. The SOAP study evaluated more than 3000 ICU patients with sepsis; a positive net fluid balance was among the strongest predictors of death.⁶¹ Multivariate regression analysis implicated positive fluid balance as an independent predictor of outcome despite disease severity. Similarly, the Vasopressin and Septic Shock Trial (VASST) investigators determined that more positive fluid balance was significantly associated with an increase in mortality.⁶² In these patients with sepsis, the cumulative mean fluid balance was 11 L fluid positive by post-enrollment day 4. In patients who received conservative fluid management after the initial resuscitation, equating to net “even” or negative fluid balance on at least two consecutive days during the first week after the onset of septic shock, lower in-hospital mortality was observed.⁶³ Volume overload is associated not only with increasing mortality but also with greater use of related medical interventions, including thoracentesis and the prescription of diuretic agents.⁵⁹

Higher cumulative fluid balance has been associated with acute lung injury (ALI), as well as ARDS.⁶⁴ Both disorders portend poorer ICU outcomes. In contrast, more conservative fluid management strategies are associated with shorter durations of mechanical ventilation and improved outcomes in patients with ALI.⁶⁵ In cancer patients admitted to the ICU, mean cumulative fluid balances exceeding 1.1 L in 24 hours were more frequently observed in the nonsurvivors.⁶⁶ Among patients admitted to the neurosurgical ICU for subarachnoid hemorrhage, positive net fluid balances after 3 days predicted the occurrence of vasospasm by transcranial Doppler and was associated with a longer length of hospital stay.⁶⁷

Volume overload is common in critically ill patients who develop AKI, particularly with oliguria. In patients who require renal replacement therapy, fluid overload at the time of dialysis initiation has been associated with a higher 90-day mortality.⁶⁸ These differences in mortality persist after adjusting for disease severity, the timing of initiation of renal replacement therapy, dialytic modality, and sepsis. Additionally, patients enrolled in the Program to Improve Care in Acute Renal Disease (PICARD) study who had evidence of volume overload when the serum creatinine concentration was at its peak had significantly lower chances of recovering kidney function; their odds ratio for death was 2.07 (95% CI, 1.27-3.37) when volume overload was present at dialysis initiation.⁶⁹ Complicating this issue is the fact that the assessment of volume overload and cumulative fluid balance is often subjective; results may be inconsistent due to errors in recording intakes and outputs and inaccurately measuring patient weights. A positive fluid balance might not correlate with clinical evidence of volume overload.⁵⁹ Furthermore, objective measurements of volume status, such as central venous pressure readings, may not always correlate with fluid balance. Additional clinical trials are necessary to further guide clinical decision making in volume administration after the initial resuscitation.

CONCLUSION

Replenishing and maintaining an adequate intravascular volume in critically ill patients remains somewhat of an art, without a universally applicable “recipe” to guide fluid replacement. Individualization of care is required, often balancing the administration of vasopressors with proper fluid repletion. Nonetheless, recent randomized trials

support several guiding principles that appear to optimize patient outcomes. In sepsis, early goal-directed fluid administration using IV crystalloids before colloids or blood products remains a mainstay of therapy in patients who lack active blood loss or symptomatic anemia. In the settings of cirrhosis with peritonitis and possibly severe burns, albumin infusion along with crystalloids may improve outcomes. Infusion of HES appears to be associated with higher complication rates, particularly AKI. Recently, prescription of chloride-containing crystalloids has begun to lose favor based on the desire to avoid the adverse effects of hyperchloremia and metabolic acidosis. Finally, excessive transfusion of packed red blood cells for sepsis-induced hypoperfusion in lieu of crystalloids appears to provide little benefit.

The threshold for transfusion is being investigated, but hemoglobin levels above 7 g/dL do not seem to improve outcomes. It remains imperative to avoid volume overload, electrolyte abnormalities, and acid-base imbalance when replenishing intravascular volume in critically ill ICU patients.

■ ACKNOWLEDGMENT

The authors wish to acknowledge Drew A. MacGregor, MD, Professor, Section of Critical Care, Pulmonary, Critical Care, Allergy, and Immunologic Medicine at Wake Forest School of Medicine, for his helpful review and critique of this chapter.

KEY POINTS

1. Prior to considering the administration of colloids or blood products in critically ill patients with an inadequate vascular volume, intravenous crystalloids remain the mainstay of volume repletion therapy (except in the settings of active bleeding or symptomatic anemia).
2. In patients with cirrhosis and accompanying peritonitis, albumin infusion along with intravenous crystalloids may improve outcomes.
3. Administration of hydroxyethyl starch appears to be associated with higher complication rates, particularly acute kidney injury.
4. Chloride-containing crystalloid infusions, including normal saline, have begun to lose favor based on their risk of inducing hyperchloremia and metabolic acidosis.
5. Excessive transfusion of packed red blood cells in patients with sepsis and hypoperfusion appears to provide little added benefit to the infusion of crystalloids alone.

The fundamental principles that govern fluid and electrolyte physiology in pediatric practice are, in many instances, similar to those in adults, particularly in older children. However, some important differences in factors affecting fluid management, mainly in infants and young children, have to be taken into account when prescribing IV fluids in this age group. In addition, many of the principles used to estimate normal fluid losses and requirements for replacement in hospitalized patients (maintenance fluids) are based on limited studies published over 50 years ago, at a time when the complexity of illness was far less than that seen today. The formulae were developed based on principles established for normal physiology and did not take into account that the hormonal influences that govern fluid and electrolyte balance may be seriously perturbed in critical illness. The challenge is now to rethink some of these principles in the light of new knowledge of how acute illness may influence them.

BODY WATER DISTRIBUTION IN CHILDREN

Body water content in children changes significantly with age.^{1,2} Total body water (TBW) is high in the fetus and preterm infant. During early fetal life, TBW represents 90% of total body weight, with 65% located in the extracellular fluid (ECF) compartment. By term, the ECF and the intracellular fluid (ICF) volume has fallen to 45% and 30% of TBW, respectively. The preterm infant commonly undergoes a relative expansion of both TBW and ECF volume and a diuresis in the first few days of postnatal life. Fractional excretion of sodium correlates inversely with age in the preterm infant, who is susceptible to both sodium loss as well as sodium and volume overload.³ In addition, the glomerular filtration rate is lower than in the term infant, and water losses caused by the large surface area-to-body weight ratio leads to considerable evaporative losses.⁴⁻⁷ Further discussion of fluid and electrolyte physiology in the preterm infant is beyond the scope of this chapter (Table 108-1).

Significant changes occur in TBW over the first year of life, decreasing from 75% of body weight at birth to 65% at 6 months and 60% at 1 year of life. Some of this loss is accounted for by an increase in body fat. By puberty TBW is approximately 60% of body weight in males, with a slightly lower percentage in females. The extracellular fluid volume decreases over the first year of life to 30% of TBW and decreases with age thereafter, reaching adult values early in childhood. The relatively high ECF volume in infancy is largely caused by the greater interstitial-lymph space. In contrast, the ICF volume remains relatively constant during childhood.

FLUID HOMEOSTASIS IN CHILDREN

To achieve normal fluid homeostasis, fluid intake must balance losses. The latter consist of urine output plus insensible losses (evaporative from the skin surface and respiratory tract), with the addition of fluid loss in the stool, which should be minimal in the absence of diarrhea. Insensible losses are mainly in the form of electrolyte-free water (EFW) from the respiratory tract (15 mL/100 kcal/day). This loss is eliminated during positive pressure ventilation. Sweat mainly contains water with a small amount of sodium, except in situations where sweat glands contain excessive amounts of sodium as in patients with cystic fibrosis.

Evaporative losses also increase with elevations in body temperature, and during thermal stress, water losses may increase to as much as 25 mL/100 kcal/day.

Obligate water excretion in the urine is dependent upon solute load and the ability to concentrate and dilute the urine. The average osmolar excretion in newborn infants receiving formula feeds is 16 to 20 mOsm/kg/day.² Infants are somewhat disadvantaged compared to older children and adults in that they cannot maximally dilute (infant, 200 mOsm/L; adult, 80 mOsm/L) and concentrate the urine (infant, 800 mOsm/L; adult, 1200 mOsm/L). In addition, the infant's high metabolic rate and the solute load from the enteral feeding formula means that they require more water excretion per unit solute. The high solute load and the limited urine-concentrating ability make them prone to significant ECF contraction (dehydration) when there are excessive amounts of water loss. Typically, this occurs in gastroenteritis where reduced oral intake is combined with excessive water and electrolyte loss in the stool (Table 108-2).

The urine is the major source of electrolyte loss in the body. The commonly used values for sodium (Na) and potassium (K) requirements in parenteral fluids in children are 2-3 mmol/kg/day and 1 to 2 mmol/kg/day, respectively.⁸ These values assume that these are the amounts of cations needed for normal homeostasis. However, in critically ill children, the urinary Na⁺ and K⁺ concentrations can be much higher.

PARENTERAL FLUIDS ADMINISTERED AS MAINTENANCE THERAPY

In the normal healthy individual water intake is regulated by thirst stimulated via osmoreceptors in the hypothalamus. Infants and small children are unable to regulate their intake because they do not have access to water for the same reasons that apply in older children or adults in coma or with reduced levels of consciousness. When oral intake is replaced by parenteral fluids in children, the amount of fluid (i.e., water) given is related to body weight and energy expenditure. In 1957 Holliday⁸ published a formula that linked body weight to energy expenditure, which formed the basis for the prescription of maintenance fluids in hospitalized children. An allowance of 100 mL/100 kcal/day was made for insensible water loss, with 66.7 mL/100 kcal/day to replace urine output. Factoring in water of oxidation of 16.7 mL/100 kcal/day leaves a total of 100 mL/100 kcal/day for replacement of normal losses (Table 108-3).

The estimates for Na⁺ (3 mmol/100 kcal/day) and K⁺ (2 mmol/100 kcal/day) in maintenance fluids were calculated using the sodium and potassium concentrations of cow's milk and breast milk.⁸ This paper became the standard reference for parenteral fluid administration in pediatrics. Although the simple mathematical calculations for obtaining these estimates were convenient, the assumptions made for the daily requirements for sodium, potassium, and EFW mandated the use of hypotonic intravenous solutions and became the universal practice in pediatric medicine over the next 50 years. However, nonphysiologic stimuli for antidiuretic hormone (ADH) secretion (pain, anxiety, narcotics, positive pressure ventilation), which inhibit the excretion of EFW, are common in critically ill patients. Therefore, it is not surprising that mild degrees of hyponatremia are a common finding in pediatric patients even before they receive parenteral fluid

TABLE 108-1 Water Content of Body Compartments in Children

| AGE | TBW (% BODY WEIGHT) | EXTRACELLULAR FLUID (% BODY WEIGHT) | INTRACELLULAR FLUID (% BODY WEIGHT) |
|---------------------|------------------------|--|--|
| Premature | 80 | 45 | 35 |
| Full-term newborn | 75 | 40 | 35 |
| 12 months to 1 year | 65 | 30 | 35 |
| 1 to 12 years | 60 | 20 | 40 |
| Adolescents | 60 | 20 | 40-45 |
| Males | 55 | 18 | 40 |
| Females | | | |

TABLE 108-2 Water Losses in Normal Children (mL/100 kcal/24 hr)

| SOURCE | NEWBORN TO 6 MONTHS | 6 MONTHS TO 5 YEARS | 5-10 YEARS | ADOLESCENTS |

therapy. In a study by Gerigk⁹ of 103 children admitted to the hospital with acute medical illnesses, the median plasma Na⁺ value was 136 mmol/L, with plasma ADH levels higher than would be expected for that degree of hyponatremia. In 31 control patients, the median serum Na⁺ level was 139 mmol/L, with lower ADH levels than those of the ill children. Similar observations were made in children admitted through a hospital emergency department who subsequently developed hospital-acquired hyponatremia. They received twice as much EFW compared with a control group of nonhyponatremic patients.¹⁰ The nonphysiologic secretion of ADH has been reported in association with many acute medical illnesses, including meningitis, bronchiolitis, encephalitis, traumatic brain injury, and gastroenteritis.¹¹⁻²² In addition, the hyponatremia that develops has been shown to be associated with an adverse outcome in children with acute bronchiolitis admitted to the pediatric intensive care unit (PICU).²³ This observation led to an increased number of publications recommending the use of isotonic or near-isotonic fluids for standard maintenance in children to avoid the potentially hazardous administration of EFW in situations where ADH secretion is not inhibited.^{10,24-27} The accumulated evidence strongly suggests that hypotonic fluids should be reserved for patients with a demonstrated need for EFW (serum Na⁺ >145 mmol/L) rather than being the default solution for pediatric patients (Table 108-4).

PARENTERAL FLUID ADMINISTERED IN THE PERIOPERATIVE PERIOD

Standard practice in perioperative fluid management is to replace intravascular volume losses with blood or colloid solutions and to use electrolyte solutions to provide for ongoing fluid requirements, replacement of evaporative losses from exposed serosal surfaces in open body cavities in thoracic and abdominal surgery, and losses from third space fluid sequestration. Extra IV fluid is also frequently administered to treat hypotension due to the vasodilating effects of anesthetic agents. The preferred electrolyte solution used in pediatric anesthesiology practice for intraoperative fluid administration is Ringer's lactate or isotonic saline because of concerns about the development of postoperative fluid retention and hyponatremia associated with elevated ADH levels.²⁸⁻³⁰ The potential for this problem is increased when hypotonic dextrose/saline solutions are used.^{29,31-33} This inability to excrete a sodium-free water load is amply illustrated in scoliosis surgery, where patients seem to be particularly at risk for the development of hyponatremia postoperatively.³⁴ Prospective studies have shown that the degree of hyponatremia is less when isotonic or near-isotonic solutions are used.^{35,36} Burrows³⁶ reported a nonrandomized trial comparing Ringer's lactate with 0.2% NaCl in a group of children following scoliosis surgery. He found that the postoperative plasma Na⁺ level fell in

both groups but that the decrease was marked in those patients receiving the hypotonic fluid. A more recent randomized trial that compared Ringer's lactate with 5% dextrose and 0.45% NaCl with 5% dextrose as a postoperative maintenance fluid in children after spinal or neurosurgical procedures observed an 18% incidence of hyponatremia ($\text{Na}^+ < 135 \text{ mmol/L}$) in the 0.45 NaCl group versus zero in the Ringer's lactate group.³⁷

The EFW retention due to nonphysiologic stimulation of ADH secretion it does not fully explain the reduction in plasma Na^+ commonly seen with Ringer's lactate. Further insights to explain this observation come from a study by Steele,³⁸ in which plasma and urine Na^+ were measured in adult patients undergoing elective surgery, all of whom received Ringer's lactate as their perioperative fluid. They found that the urine Na^+ concentration was consistently above 150 mmol/L and as high as 350 mmol/L in some instances. This was associated with a significant positive water balance and a fall in the plasma Na^+ , a process they termed *postoperative desalination*. In a similar study of children undergoing elective surgery, all of whom received Ringer's lactate, we found similar levels of urinary Na^+ loss (unpublished observations). This desalination process is consistent with the kidney's attempts to deal with a volume overload after the vasodilating effects of anesthetic agents are no longer present but ADH is still being actively secreted. In this situation, it would be unwise to prescribe hypotonic fluids in the postoperative period and impose an extra burden of more EFW to be excreted by the kidney.

Further evidence has now emerged that supports the use of isotonic rather than hypotonic fluid in the perioperative period. A prospective observational study in patients admitted to the PICU postoperatively documented an increased risk of the development of hyponatremia associated with the use of hypotonic saline due to water retention and increased sodium excretion.³⁹ Several recent prospective randomized trials have compared the use of isotonic with hypotonic saline in a postsurgical population. These studies have shown that the incidence of hyponatremia was significantly decreased by the use of isotonic saline, without the development of hypernatremia.⁴⁰⁻⁴² There is now clear evidence that the use of hypotonic saline in the perioperative period places patients at risk of developing acute hyponatremia.

THE MANAGEMENT OF ACUTE WATER AND ELECTROLYTE DEFICITS IN CHILDREN

The three most common conditions for which IV fluids are used to replace volume loss in critically ill children are DKA, acute gastroenteritis, and septic shock.

Water and Electrolyte Deficits in Diabetic Ketoacidosis (DKA)

Diabetic ketoacidosis is characterized by losses of water and electrolytes caused by hyperglycemia-induced osmotic diuresis. The high osmolality of the ECF results in the shift of water from the ICF compartment across the cell membrane. A study of adults with type I diabetes for whom insulin therapy was withheld showed fluid deficits of 5 to 10 liters together with up to 20% loss of total body sodium and potassium.⁴³ At the time of presentation, patients are ECF contracted; clinical estimates of the deficit are usually in the range of 7% to 10%, although shock with hemodynamic compromise is a rare event in DKA in children. The hyperglycemia in DKA results in a hyperosmolar state, but the serum Na^+ concentration is an unreliable measure of the degree of ECF contraction due to the dilutional effects of the fluid shift from the ICF to the ECF compartment. The *effective* osmolality (PeffOsm), calculated as $(2 [\text{Na}^+ + \text{K}^+] + [\text{glucose}])$, all in mmol/L, at the time of presentation is frequently in the range of 300 to 350 mOsm/L. An elevated hematocrit may be a useful marker of severe ECF contraction. Urea is not used in the calculation of PeffOsm because it moves freely across the cell membrane. An estimate of true ECF deficit can be made

by correcting the measured serum Na^+ for the increase in ECF water using the formula developed by Katz:⁴⁴

$$\text{Na}^+ + \frac{([\text{Glucose (mmol/L)}] - 5.6)}{5.6} \times 1.6$$

The ECF contraction is associated with a reduction in GFR that results in reduced glucose and ketone clearance from the blood and worsening DKA. Studies in humans have shown that IV fluid administration alone results in substantial decreases in blood glucose even before insulin has been given because of the increase in GFR.⁴⁵ The serum K^+ is also frequently elevated at the time of presentation⁴⁶ but falls rapidly as GFR increases and insulin reprimed the Na/K/ATPase cell membrane pump.⁴⁷

Cerebral edema is the most important potentially life-threatening event seen in children with DKA. The reported occurrence rate in the pediatric literature varies between 0.2% and 1%.⁴⁸⁻⁵¹ However, this number is likely to be an underestimate, as it is based on retrospective reviews that rely on the clinical diagnosis of increased intracranial pressure. The incidence is also reported to be higher in new-onset diabetes and in younger children.^{48,51,52} Series of brain imaging studies in children with DKA have shown decreased ventricular size (increased ICP) either early (<12 hr) in the treatment course⁵³ or even before therapy has commenced.⁵⁴ The ultimate consequence of this is brainstem herniation. The total adverse outcome rate (death or permanent neurologic injury) in cerebral edema associated with DKA (CE-DKA) is as high as 40% to 50% in some series, with few intact survivors where brainstem herniation has occurred.^{48,55} For these reasons, children with severe DKA ($\text{pH} < 7.2$) should be admitted to the ICU for close monitoring of CNS status during the first 24 hours of fluid deficit correction and acid-base disturbance. Symptoms such as diminished level of consciousness, headache, and vomiting are signs of impending cerebral edema.

Many hypotheses have been proposed to explain brain swelling in association with DKA, including overzealous rehydration with hypotonic IV fluids, the rapid reduction of blood glucose with insulin, activation of the Na/H transporter system, change in oncotic pressure, increased permeability of the blood-brain barrier, and changes in cerebral blood flow. Most of these hypotheses are based on individual case reports or small case series. Although the precise cause is not fully understood, there is general agreement that the pathogenesis of CE-DKA involves an osmolar shift that results in fluid accumulation in the ICF compartment and cell swelling. Changes in serum osmolality as a risk factor have been identified in several series. A rapid reduction in the PeffOsm caused by either a fall in blood glucose or serum Na^+ or both is associated with the rapid administration of IV fluid and possibly by the use of bolus dose insulin.⁵⁶ The consequence is that water follows the osmotic gradient back into the ICF compartment. Other risk factors that were identified for the development of cerebral edema in a large retrospective series, which included age-matched controls, were a low PaCO_2 and a high urea at the time of presentation.⁵¹ These parameters are probably reflective of the severity of the acidosis and ECF contraction.

In the absence of a single unifying hypothesis as to the cause of cerebral edema in DKA, it is not possible to mandate a definitive treatment approach that will predictably prevent CE-DKA. It remains likely that the pathogenesis of CE-DKA is multifactorial in nature and includes both patient- and treatment-related factors. The objective of treatment should be the gradual reduction in serum osmolality, which can be achieved by conservative fluid resuscitation and the avoidance of hypotonic fluids in the initial resuscitation period. Current consensus guidelines⁵⁷ do not recommend the use of an IV fluid bolus but that initial replacement of 10 mL/kg of isotonic saline be given over 1 to 2 hours followed by an insulin infusion at 0.05 to 0.1 U/kg/hr. Potassium is added as the calculated deficit recovers over 48 hours. A guiding principle is that failure of the serum Na^+ to rise during IV fluid replacement indicates too rapid a rate of fluid infusion and the risk of CE-DKA. It remains to be seen whether this approach will lower the risk of cerebral edema associated with the onset and management of

DKA in children. A retrospective study from our center demonstrates that the use of isotonic saline with the associated rise in serum sodium as serum glucose decreases protects against the development of cerebral edema.⁵⁶

Children presenting with DKA require close monitoring for changes in the level of consciousness and other signs of increased ICP, such as headache and vomiting. This level of care is best provided in an ICU setting. In the event that cerebral edema is suspected, the serum osmolality should immediately be raised by the administration of mannitol (1 gm/kg IV)⁵⁸ or 2 to 3 mL/kg of 3% saline⁵⁹ and a decrease in the IV fluid and insulin infusion. These measures should be taken without waiting for a CT scan, which may fail to demonstrate cerebral edema.

Fluid and Electrolyte Deficits in Gastroenteritis

Acute gastroenteritis is the most common cause of disturbed fluid and electrolyte homeostasis seen in childhood. Infants with diarrhea are particularly vulnerable to significant losses of fluid, sodium, chloride, and bicarbonate from the small intestine and present with what is frequently classified as either hypotonic, isotonic, or hypertonic dehydration based on the serum Na^+ level. This terminology is technically incorrect, as only in the hypertonic form is there loss of fluid from the ICF compartment; these patients are truly dehydrated. Patients with diarrheal illnesses associated with fluid loss with normal or reduced serum Na^+ have loss of TBW and ECF, with normal or increased ICF volume.⁶⁰ Infants with severe hypernatremic dehydration are at greatest risk of an adverse neurological event, but seizures from severe hyponatremia have been reported in infants presenting with acute gastroenteritis caused by the administration of oral salt-free fluids as a replacement.^{11,61,62} The degree of ECF deficit is usually assessed on clinical grounds using the time-honored clinical signs of capillary refill time, dry mucous membranes, and skin turgor.⁶³ However, these signs are open to subjective interpretation, and there may be a tendency to overestimate the degree of ECF contraction in less severely ill children. In a study by Mackenzie,⁶⁴ the fluid deficit in children with gastroenteritis and mild to moderate dehydration was overestimated, resulting in the overuse of IV fluids. Skin turgor, increased capillary refill time, high urea, low pH, and increased base deficit all correlated with the degree of ECF contraction but not the presence of thirst or oliguria. Other studies have shown that a reduced serum bicarbonate concentration is the most common electrolyte abnormality associated with significant ECF contraction in gastroenteritis.^{65,66}

Patients with gastroenteritis whose serum is isotonic and hypotonic should be managed with isotonic or near-isotonic saline (Ringer's lactate), while those who are significantly hypertonic may receive solutions that contain some EFW. An observational study found that ADH levels are frequently elevated in these patients.⁶⁷ A randomized controlled trial of IV fluid rehydration in children with gastroenteritis showed that the use of isotonic saline protected against the development of hyponatremia without the development of hypernatremia when compared with hypotonic solutions.²² Infants with severe hypernatremia should have their free water deficit corrected slowly because of the danger of rapid fluid shift to the ICF compartment. There is an increasing trend to rapidly rehydrate patients with gastroenteritis with IV solutions in the emergency department before discharging them.^{68,69} A simpler and more effective technique is to use oral rehydration therapy (ORT), which has a proven efficacy in clinical trials of patients with acute gastroenteritis. These solutions contain Na^+ concentrations between 45 and 90 mmol/L.⁶⁹⁻⁷²

Fluid Deficit Replacement in Sepsis and Septic Shock

The importance of early IV fluid resuscitation in sepsis and septic shock in children was established in the landmark study by Carcillo in 1991⁷³ and forms the basis of published guidelines for the administration of fluid boluses of 20 mL/kg of isotonic saline or an equivalent colloid solution to patients in shock.⁷⁴ Although this remains a key

recommendation for the early treatment of sepsis in the most recently published Surviving Sepsis guidelines,⁷⁵ this approach may not be applicable to all patients. A large randomized trial in resource-limited countries in Africa, which included children with malaria, showed increased mortality in patients who received IV bolus fluid therapy compared to those who did not receive IV fluid resuscitation.⁷⁶ However, unless further evidence emerges to confirm this finding, IV bolus fluids remain one of the cornerstone treatments for children with sepsis. What remains unresolved is which fluid is preferred in such situations. Guideline recommendations suggest that either 0.9 NaCl or Ringer's lactate can be used, but increasing evidence suggests that a balanced salt solution may have some advantages because of the reduced chloride load and higher pH.

BALANCED SALT SOLUTIONS IN PEDIATRICS

In 1934, the pediatrician and biochemist Alexis Hartmann developed a solution to treat gastroenteritis and dehydration in children using Ringer's solution and buffered with lactate. Ringer's lactate or Hartmann's solution, with its lower sodium concentration and higher pH, is widely used in pediatric anesthesia practice but less so as a maintenance fluid in other hospitalized children. The increasing awareness of the dangers associated with the use of hypotonic saline together with concerns about the high chloride concentration in 0.9 NaCl has made this near-isotonic solution an attractive option. An alternative balanced saline solution, PlasmaLyte 148, is now available in some parts of the world. This solution has the same sodium concentration as isotonic saline, with lower chloride and a higher pH. It is now being used in Australasia and the UK as a maintenance fluid in anesthesia and for nonsurgical and PICU patients⁷⁷⁻⁷⁹ but is not yet licensed by the FDA for use in children (Table 108-5).

DISORDERS OF SODIUM HOMEOSTASIS

Sodium is the principal cation of the ECF compartment. Movement of Na^+ into the ICF compartment is reversed by activation of the Na/K/ATPase pump. Sodium is absorbed in the proximal tubule under the influence of aldosterone. The serum Na^+ reflects the osmolality and the ECF water volume, which is tightly regulated by ADH secretion.

Hyponatremia

Hyponatremia (serum $\text{Na}^+ < 136$ mmol/L) is the most common electrolyte disorder seen in the hospitalized population and implies an expansion of the ICF compartment. It is caused by either water gain (e.g., use of hypotonic fluids) or salt loss (e.g., gastroenteritis) (Table 108-6).

Acute hyponatremia, defined as a fall in plasma Na^+ to less than 130 mmol/L within 48 hr, leads to rapid movement of water from the ECF to the ICF compartment and can cause cerebral edema, with

TABLE 108-5

SALT LOSS

Gastroenteritis
Cerebral salt wasting

catastrophic outcomes reported in children.^{31,80,81} The clinical findings include elevated intracranial pressure (nausea, vomiting, headache), and the condition is frequently undiagnosed until the onset of seizures. This event is usually followed by apnea, indicating that brainstem coning has occurred. Acute symptomatic hyponatremia (seizures, etc.) rarely occurs at serum Na^+ levels greater than 130 mmol/L, but when it does, it constitutes a medical emergency. The primary objective is to raise serum Na^+ above this level to prevent brainstem herniation, which can be most effectively achieved by the administration of hypertonic (3%) saline.⁸² Once this threshold has been reached, the serum Na^+ can be allowed to correct by fluid restriction with or without the use of furosemide. Intravenous mannitol has also been used successfully in the emergency treatment of acute symptomatic hyponatremia.⁸³

Acute hyponatremia is an iatrogenic abnormality seen in pediatrics, most commonly due to excess administration of EFW in hypotonic saline solutions used as maintenance in this population. The use of isotonic saline provides a physiologic rationale to reduce the risk of this potentially life-threatening complication but has not been used because of concerns about the administration of excess sodium. Compelling evidence has now emerged from randomized trials both in postsurgical and nonsurgical populations demonstrating that isotonic saline reduces the incidence of acute hyponatremia compared with hypotonic saline without the development of hypernatremia.^{41,42,77,84} Continuing to use hypotonic saline in a pediatric population puts patients at risk for the development of acute hyponatremia.⁸⁵

Chronic hyponatremia is a common finding in patients with heart failure and renal failure and is associated with increased total body water and salt retention. It is not associated with cerebral edema, and correction of chronic hyponatremia by rapid infusion of isotonic or hypertonic saline should not be attempted because such treatment is associated with brain damage secondary to central pontine demyelination.⁸⁶⁻⁸⁸

Hypernatremia

Hypernatremia is defined as a serum Na^+ greater than 145 mmol/L and is caused by either water deficit or salt gain. The former is seen in infants with severe gastroenteritis, with a loss of water in excess of sodium, sometimes compounded by increased solute intake from incorrect mixing of infant formula. The absence of ADH secretion causing diabetes insipidus is seen in patients with pituitary tumors, traumatic brain injury, and CNS infections.⁸⁹⁻⁹² Water loss in critically ill children may also be associated with the use of loop diuretics or mannitol. Hypernatremia secondary to salt gain is seen with the excessive use of hypertonic saline solutions or with the administration of IV bicarbonate.

A rise in serum Na^+ is associated with the movement of water from the ICF to the ECF compartment and the development of a hyperosmolar state. Brain cells adapt with an increase in electrolytes and ideogenic osmoles (inositol, taurine), which tends to mitigate the fluid shift with partial restoration of intracellular osmolality and brain cell volume.⁹³⁻⁹⁵ Levels of Na^+ greater than 165 mmol/L are frequently associated with abnormal CNS findings, and there is an increased risk of

TABLE 108-7 Causes of Hypernatremia**WATER LOSS**

SALT GAIN

Use of high Na^+ -content solutions (hypertonic saline, intravenous bicarbonate)
Hypertonic enteral feeding formulas
Cathartic agents

subdural hemorrhage and infarction in infants with hypernatremic dehydration.⁹⁶⁻⁹⁹ There is also the added danger of brain edema developing during the attempt to correct these hyperosmolar states rapidly with the use of solutions that are hypoosmolar compared to the ICF compartment.¹⁰⁰⁻¹⁰⁵ Published recommendations suggest that the rate of correction of serum Na^+ should be less than 0.5 mmol/L/hr using the following formula for correction, which estimates the effect of 1 liter of any infusate on serum Na^+ .

$$\text{Change in serum Na}^+ = \frac{\text{infusate Na}^+ - \text{serum Na}}{\text{TBW} + 1}$$

In severe hypernatremia (serum $\text{Na}^+ > 170$ mmol/L), it is recommended that the maximum not be corrected to below 150 mmol/L in the first 48 to 72 hrs.¹⁰⁶

The epidemiology of hypernatremia in children has changed recently from gastroenteritis with dehydration as the principal cause to one of a hospital-acquired problem in association with either excess salt administration or a free water deficit. In a study by Moritz of children with a serum Na^+ greater than 150 mmol/L, the problem was hospital acquired in 60% of cases, and the mortality was 11%.¹⁰⁷ In a similar series of adult patients, the ICU mortality rate for patients with plasma Na^+ levels greater than 150 mmol/L was 30%¹⁰⁸ (Table 108-7).

CHLORIDE

Chloride is the principal anion of the ECF compartment. It is filtered at the glomerulus, and 80% is reabsorbed in conjunction with sodium in the proximal tubule. It is also reabsorbed in the ascending limb of the loop of Henle, a process that is blocked by furosemide. Chloride is exchanged for bicarbonate in the distal tubule. In ECF volume depletion, excess Cl^- , along with Na^+ , is reabsorbed in the proximal tubule, resulting in lower distal delivery and less HCO_3^- secretion. With chloride depletion, less Na^+ is reabsorbed in the proximal tubule. Increased distal delivery results in increased exchange with K^+ and H^+ . This contraction alkalosis is invariably associated with hypochloremia, most commonly caused by the overuse of loop diuretics. Hypochloremia is also caused by gastric suctioning and respiratory acidosis. In addition, many of the conditions that cause hyponatremia also result in hypochloremia.

Hyperchloremia is seen in association with respiratory alkalosis, hypernatremic dehydration, and the administration of large volumes of isotonic saline. The use of large amounts of isotonic saline during fluid resuscitation can result in hyperchloremic metabolic acidosis.¹⁰⁹ If the serum Cl^- is not measured, an increased base deficit could be wrongly interpreted as indicating inadequate volume resuscitation in shock.¹¹⁰

Plasma chloride measurements are an integral part of the calculation of the anion gap, which is important for the diagnosis of metabolic acidosis.¹¹¹ This value is the difference between the measured cations (Na^+) and anions ($\text{Cl}^- + \text{HCO}_3^-$), which is normally in the range of 12 to 16. The anion gap increases when unmeasured anions such as lactate

and accumulated β -hydroxybutyrate in DKA are present. A normal or reduced anion gap acidosis is seen in association with hyperchloremia from saline administration or other situations in which serum Cl^- is elevated.^{109,112,113}

POTASSIUM

Potassium is the major cation of the ICF compartment, with an intracellular concentration of 150 mmol/L. Measurement of serum K^+ reflects the ECF concentration, which is only 2% of the total body K^+ . The gradient between the ICF and ECF compartments is maintained by activation of the $\text{Na}^+/\text{K}^+/\text{ATPase}$ pump in the cell membrane. The movement of K^+ from the ECF to ICF compartment is enhanced by insulin, hypothermia, alkalosis, catecholamines, and β -agonist therapy.

Potassium filtered at the glomerulus is reabsorbed in the proximal tubule and the thick ascending limb of the loop of Henle. It is secreted in the distal nephron under the influence of aldosterone, plasma K^+ concentration, and urine flow rate.

Hypokalemia

Hypokalemia in children is commonly seen with gastroenteritis and diarrhea, where ECF contraction leads to stimulation of aldosterone secretion. There is also total body potassium depletion in DKA, although the initial measured level is high due to acidosis.⁴⁶ Adolescents with anorexia nervosa can present with profound degrees of hypokalemia, which is a known cause of sudden death in this syndrome.¹¹⁴ In the critical care setting, hypokalemia is most commonly associated with diuretic use, nasogastric suction, hypomagnesemia, and metabolic alkalosis. In acute metabolic alkalosis, each 0.1-unit rise in pH results in a decrease of 0.2 to 0.4 mmol/L in serum K^+ .¹¹⁵ In chronic metabolic alkalosis, K^+ is exchanged for H^+ in the distal nephron. Increased K^+ output in the urine is also associated with renal tubular defects (Bartter's syndrome, renal tubular acidosis) and the use of drugs such as amphotericin, ticarcillin, carbenicillin, and steroids.¹¹⁶

Potassium supplementation therapy in the critical care setting is usually in the form of KCl, as there is frequently an associated Cl^- deficiency. Acetate and phosphate can be used as alternative anions in the hyperchloremic state (e.g., DKA).

The clinical manifestations of hypokalemia include muscle weakness (which may prolong the effect of neuromuscular blockers), intestinal ileus, and cardiac arrhythmias. The latter are rarely a problem except in children with congenital heart disease, particularly in the post-cardiopulmonary-bypass setting. The potential for digoxin toxicity is enhanced with hypokalemia. In situations where hypokalemia needs to be treated in the setting of fluid restriction, high-concentration K^+ infusions (up to 0.5 mmol/mL) can be infused through central lines, with frequent measurements of serum K^+ levels. Hypokalemia may remain resistant to treatment when significant hypomagnesemia is present.

Hyperkalemia

Hyperkalemia is caused by either failure of potassium excretion (renal failure) or in the movement of K^+ from the ICF to the ECF compartment. Common causes of the latter include cellular breakdown or injury in tumor lysis syndrome, rhabdomyolysis, burns, and trauma. The use of the depolarizing neuromuscular blocker succinylcholine in this setting or in patients with muscle dystrophy or spinal cord injury

can lead to an abrupt rise in serum K^+ and cardiac arrest. Severe hyperkalemia is also seen in malignant hyperthermia, caused by a combination of hemolysis and acidosis. Both captopril and propranolol can cause hyperkalemia by decreasing aldosterone synthesis. Propranolol also blocks β -adrenergic-mediated movement of K^+ across the cell membrane. Acute metabolic acidosis also results in a rapid movement of K^+ from the ICF to ECF compartment, and severe hyperkalemia is frequently seen during cardiac arrest and CPR without necessarily implying causality.

Acute hyperkalemia represents a medical emergency, and serum levels in excess of 6 mmol/L can result in cardiac arrest and sudden death, particularly in the post-cardiopulmonary-bypass setting. Frequently, the only clinical manifestation is the finding of tall-peaked T waves and widening of the QRS complex on the EKG tracing, but the absence of these findings does not exclude the diagnosis. Patients with borderline high levels of serum K^+ can develop life-threatening hyperkalemia with the development of acidosis. As it is the extracellular K^+ level that is harmful, emergency measures should be directed at increasing the transmembrane flux from ECF to the ICF compartment. Such measures include the use of bicarbonate to correct acidemia, β -agonist therapy, and glucose/insulin administration.^{115,117} The use of IV calcium chloride will help protect the heart against the development of cardiac rhythm disturbances. These are temporizing measures while steps are taken to increase K^+ removal from the body, either by using sodium/potassium exchange resins (rectally or via NG tube) or acute dialysis.

CALCIUM

The ECF concentration is maintained under the control of vitamin D, parathyroid hormone, and calcitriol. The majority is in the bone, and in the absence of parathyroid hormone, there is reduced calcium reabsorption from bone and increased urinary secretion because of the decreased renal production of calcitriol. Forty percent of the calcium is protein bound, and the most common cause of a low total calcium in critically ill children is hypoalbuminemia. In this situation, the ionized level is normal. Conversely, the ionized level is reduced when there is increased protein binding.

Hypocalcemia is seen in neonates with birth asphyxia, preterm infants, term newborns in the first week of life, and infants of diabetic mothers. This finding is invariable in newborn infants with DiGeorge syndrome, where it is seen in association with conotruncal congenital heart defects, typically truncus arteriosus and an interrupted aortic arch. The majority of these infants have microdeletions of the long arm of chromosome 22 (22q minus syndrome) and immunodeficiency. For this reason, all transfused blood products should be irradiated. Hypocalcemia is a common finding in critically ill older children, with a reported incidence of 49% in one study.¹¹⁸ Causes include cardiopulmonary bypass, the use of citrated blood and blood products, albumin transfusions, burns, sepsis, the use of loop diuretics, and aminoglycosides. Hyperphosphatemia, seen in tumor lysis syndrome and renal failure, can also result in hypocalcemia.

Hypercalcemia in critically ill children is usually the result of excessive calcium administration frequently in association with diuretic administration. The end result may be the development of nephrocalcinosis. Other less common causes include neonatal severe primary hyperthyroidism caused by mutations of the CaSR gene and Williams syndrome, where it is associated with supravalvular aortic stenosis and peripheral pulmonary artery stenosis.

Acute kidney injury (AKI) is recognized as one of the most serious complications in critically ill patients. AKI is strongly associated with higher short- and long-term mortality, increased resource utilization, and a higher risk for the development of chronic kidney disease (CKD). AKI is characterized by an abrupt decrease in the glomerular filtration rate (GFR) that results in the accumulation of nitrogenous waste products and an inability to maintain fluid and electrolyte homeostasis.¹ AKI can result from decreased renal perfusion not severe enough to cause cellular injury, such as an ischemic, toxic, or obstructive injury of the renal tubule, tubulointerstitial process with inflammation and edema, or a primary reduction in the filtering capacity of the glomerulus.

If renal tubular and glomerular function is intact, but solute clearance is limited by factors compromising renal perfusion, the injury is termed *prerenal azotemia*. If renal dysfunction is related to an obstruction of the urinary outflow tract, it is termed *postrenal azotemia*. AKI due to a primary intrarenal cause is called *intrinsic renal injury* or *renal azotemia*. Prerenal azotemic and intrinsic renal injury due to sepsis, ischemia, and nephrotoxins are responsible for most episodes of AKI.^{2,3}

Renal blood flow is approximately 1200 mL/min and constitutes 20% of cardiac output. Given this apparently generous perfusion, it may seem surprising that the kidneys are so susceptible to hemodynamic insults. The majority of perfusion (80%-90%), however, is to the renal cortex, where glomerular filtration occurs. The medulla is designed to concentrate and dilute urine. During urine concentration, the high osmotic gradient required for the reabsorption of water is associated with a low rate of blood flow. In fact, oxygen tension in the outer medulla in the region of the metabolically active thick ascending limb of Henle is only around 10 mm Hg.⁴ This combination of low blood flow and diminished oxygen tension in a metabolically active environment makes the kidneys very susceptible to ischemic injury.

■ PRERENAL CAUSES OF AKI

Prerenal azotemia is a consequence of the reduction in renal perfusion without cellular injury. As such, this is a reversible process if the underlying cause is corrected. It may be secondary to decreased blood volume (e.g., vomiting, dehydration, and hemorrhage), or it may be due to a reduction in the effective arterial blood volume (e.g., congestive heart failure and cirrhosis). Further, the administration of medications that interfere with the normal autoregulatory ability of the kidney can contribute to prerenal azotemia. In settings of diminished renal perfusion, the administration of nonsteroidal antiinflammatory drugs (NSAIDs) or renin-angiotensin-aldosterone system (RAAS) inhibitors can precipitate overt prerenal azotemia.³

During prerenal azotemia, the RAAS becomes activated secondary to a decrease in renal blood flow accompanied by increased activity of the adrenergic nervous system. Increased levels of angiotensin II and adrenergic activation increase proximal reabsorption of sodium, whereas aldosterone increases sodium reabsorption in the distal tubule. Together, these actions decrease the urine sodium concentration to less than 20 mmol/L and fractional excretion of sodium (FE_{Na}) to less than 1%.⁵

Prerenal azotemia accounts for approximately 70% of community-acquired cases of AKI⁶ and 40% of hospital-acquired cases.⁷ Therefore,

prerenal causes should be excluded in all cases of AKI. Therapy of prerenal AKI involves reversing the underlying cause, such as volume replacement or discontinuation of offending agents.

■ POSTRENAL CAUSES OF AKI

Postrenal AKI occurs when there is a bilateral (or unilateral in the case of a single kidney) obstruction of urine flow. In this setting, intratubular pressure increases and, in turn, decreases the net glomerular filtration pressure. Obstruction of urine flow is a relatively uncommon cause of AKI and is more frequent in the community than in the intensive care unit (ICU). Several case series have placed the incidence of postrenal AKI at 3% to 25% of all cases of AKI.^{8,9,10} Postrenal AKI can be divided into renal and extrarenal causes. Extrarenal causes include prostatic disease, pelvic malignancy, and retroperitoneal disorders. Intrarenal causes include crystal deposition, as occurs in ethylene glycol ingestion or uric acid nephropathy in tumor lysis syndrome. Cast formation and tubular obstruction also occur in light-chain diseases, such as multiple myeloma.

Possible postrenal causes of AKI should be evaluated with renal ultrasonography and the measurement of postvoid residual urine in the bladder (>50 mL is abnormal). It is important to rule out these causes rapidly because the potential for renal recovery is inversely related to the duration of obstruction.¹¹

■ INTRARENAL CAUSES OF AKI

Intrarenal causes of AKI can be classified according to the anatomic location of the injury: glomerulus, vasculature, interstitium, or tubule. Suspicion of glomerulonephritis or vasculitis should be raised in a patient with renal failure who has an active urine sediment with red cells and red cell casts. In contrast, acute interstitial nephritis classically presents with pyuria and white cell casts in the urine; on occasion, hematuria is also present. Most cases of AKI from interstitial nephritis are drug related, commonly due to antibiotics or NSAIDs. Recovery usually occurs with the removal of the offending agent and may be hastened by a short course of steroids, such as 60 to 80 mg of prednisone for 10 days. The most common cause of intrinsic renal failure is acute tubular necrosis (ATN).³ Specific causes of ATN can be broadly classified as hemodynamically mediated, such as in prolonged prerenal azotemia, hypotension, and sepsis, or toxic, secondary to antibiotics, chemotherapeutic agents, and contrast media. Concerns have been raised regarding the accuracy of the term *acute tubular necrosis* given that it is a histologic diagnosis that is rarely confirmed by biopsy.¹²

The most common cause of AKI in critically ill patients is sepsis. The pathophysiology of sepsis-induced AKI remains incompletely understood. Until recently, sepsis-induced AKI was considered primarily a disease of the renal macrocirculation¹³ resulting from global renal ischemia, cellular damage, and ATN. However, an increasing body of evidence suggests that AKI in the setting of sepsis can occur in the absence of hypoperfusion.^{14,15} A consistent finding in septic patients, independent of the severity of AKI, is the presence of microcirculatory dysfunction, inflammation, and adaptive bioenergetic response to injury. The role of these mechanisms in the genesis of sepsis-induced AKI and the potential therapeutic implications have been discussed.¹⁶

TABLE 109-1 Laboratory and Microscopic Findings in Prerenal Azotemia and Acute Tubular Necrosis

| LABORATORY TEST | PRERENAL AZOTEMIA | ACUTE TUBULAR NECROSIS |
|---|---------------------------------|--|
| Urine osmolality (mOsm/kg H ₂ O) | >500 | <400 |
| Urine sodium (mEq/L) | <20 | >40 |
| Urine plasma/creatinine ratio | >40 | <20 |
| Fractional excretion of sodium (%) | <1 | >2 |
| Urinary sediment | Normal, occasional hyaline cast | Renal tubular epithelial cells, granular and muddy brown casts |

Data from Esson ML, Schrier RW. Diagnosis and treatment of acute tubular necrosis. *Ann Intern Med* 2002;137:744-52.

Differentiation of ATN from prerenal azotemia can be aided by evaluating urinary indices (Table 109-1).¹⁷ In established ATN, the tubular function is impaired, and tubular sodium reabsorption is hindered. This results in a urine sodium value greater than 40 mmol/L and FE_{Na} greater than 2%. Urine concentrating ability is also abnormal, resulting in isosthenuria with a urine osmolality less than 350 mOsm/kg H₂O.¹⁸ However, a low FE_{Na} may be seen in entities causing ATN (e.g., rhabdomyolysis and myoglobinuria),¹⁹ as well as in contrast-mediated AKI²⁰ and sepsis.²¹ In patients with prerenal azotemia who are treated with diuretics that may affect FE_{Na}, fractional excretion of urea (FE_{Urea}) or a urine-to-plasma ratio of creatinine may be more discriminatory. An FE_{Urea} less than 35% or a urine-to-plasma ratio of creatinine higher than 15 is indicative of prerenal azotemia.²² However, in patients with AKI who received diuretics, the distinction between transient and persistent AKI cannot be made accurately using FE_{Urea} because it lacks specificity.²³ An increasingly common form of AKI in the hospital is secondary to the use of contrast media. Nash and colleagues found contrast nephropathy to be the third most common form of AKI in the hospital.⁷ The pathogenesis of AKI in this setting involves both the hemodynamic and toxic effects of contrast. Contrast media cause renal vasoconstriction and medullary ischemia, as well as direct tubular toxicity.²⁴ Patients with preexisting renal disease and diabetes are at high risk, as are patients who are volume depleted.

■ **EPIDEMIOLOGY AND OUTCOMES**

Several definitions of AKI have recently been proposed. When the risk, injury, failure, loss, and end-stage renal failure (RIFLE) criteria are employed, AKI is a common complication occurring in up to a third of ICU patients and is usually a manifestation of multiorgan failure syndrome.²⁵⁻²⁷ A retrospective cohort study of 31,970 hospitalizations at an academic medical center sought to define AKI stages according to Kidney Disease: Improving Global Outcomes (KDIGO) and other criteria, and AKI incidence was 18.3%. AKI according to all definitions was associated with a significantly higher risk of death and resource utilization.²⁸ The most common cause of intrinsic renal failure is ATN.³ In a large prospective analysis by Liano and coworkers, sepsis was the most common cause (35%); postsurgical (25%) and toxic (31%) causes were also common.¹⁰ Many, if not most, patients have a multifactorial cause of AKI (Fig. 109-1). Recent data also indicate that even transient perturbations in kidney function in hospitalized patients increase the risk of death.²⁹ In a study by Thakar et al.,³⁰ the risk of death increased with the increasing severity of AKI: Acute Kidney Injury Network (AKIN) stage 1, odds ratio (OR) 2.2; stage 2, OR 6.1; and stage 3, OR 8.6 (see AKIN staging below). Furthermore, evidence suggests that a substantial percentage of patients who suffer from AKI do not return

to normal renal function.³¹ AKI is now increasingly recognized as having a bidirectional relationship with CKD in hospitalized patients. Although preexisting CKD increases the susceptibility toward the development of AKI, AKI has also been found to accelerate the development of CKD.³² Moreover, AKI superimposed on CKD leads to end-stage renal disease (ESRD) at a higher frequency than AKI alone. Despite improving supportive interventions in the ICU, the mortality rate for AKI, particularly ATN requiring dialysis, has not changed in the past three decades, remaining at 40% to 80% depending on the study.³³ The risk of developing AKI in the ICU was evaluated by de Mendonca and associates, who found that seven characteristics, if present on admission, were associated with an increased risk of developing AKI (Table 109-2).³⁴ Several other studies addressed the risk factors for mortality in the setting of AKI.^{7,10,35} As indicated in Table 109-3, the risk of death in those with AKI is increased by the presence of nonrenal organ failure, more severe renal dysfunction, as indicated by oliguria, sepsis, advanced age, and male gender. Liano and colleagues found that as the number of organ failures increased, mortality increased.¹⁰ With two organ failures, mortality was 53%, increasing to 80% with three organ failures and 100% with five organ failures. Data clearly show that patients, especially those in the ICU, are dying of AKI and not with AKI alone. The detrimental effects of AKI are not limited to the well-known classical symptoms, such as fluid overload and electrolyte abnormalities. AKI can also cause problems that are not readily appreciated at the bedside and can extend well beyond the ICU stay. Experimental and small observational studies provide evidence that AKI negatively affects innate immunity and is associated with higher rates of infection.³⁷

■ **DEFINITION**

AKI is the abrupt decrease in GFR with resultant retention of urea and other nitrogenous waste products along with dysregulation of body fluids and electrolytes. The term *acute kidney injury* was proposed by the Acute Kidney Injury Network (AKIN) as an alternative to acute renal failure (ARF) to encompass the entire range of failure based on data showing that a small change in serum creatinine influences

FIGURE 109-1 ■ Pathophysiology of ischemic acute kidney injury: events in endothelial cell activation, injury, and reduced microvascular flow. (A) Ischemia causes upregulation and expression of genes encoding various cell surface proteins, such as E-selectin, P-selectin, vascular cell adhesion protein 1, and intercellular adhesion molecule 1, as well as the downregulation of thrombomodulin. Activated leukocytes bind to endothelial cells through these adhesion molecules. Endothelial injury increases the production of endothelin-1 and decreases endothelium-derived nitric oxide synthase, which induces vasoconstriction and platelet aggregation, promoting a hypercoagulable environment. The combination of leukocyte adhesion and activation, platelet aggregation, and endothelial injury serves as the basis for vascular congestion of the cortical and medullary microvasculature. Permeability defects between endothelial cells occur as a result of alterations in tight junctions and adherens junctions. The proximity and crosstalk between the epithelial proximal tubular cells and microvascular endothelial cells, as well as the release of cytokines and chemokines, further increase inflammation. Dendritic cells also have a role in this inflammatory cascade and amplify the inflammatory signals between endothelial cells and epithelial cells. **(B)** Hematoxylin and eosin stain of a human kidney biopsy from a patient with AKI following an ischemic injury. Pathophysiology of ischemic acute kidney injury. *Nat Rev Nephrol* 2011;7(4):189-200.)

outcome. The Acute Dialysis Quality Initiative (ADQI) group proposed a consensus categorized definition, the RIFLE criteria,³⁸ which was validated and shown to correlate with hospital mortality and patient outcomes in several populations in large international databases. Subsequently, AKIN proposed a revision of the RIFLE criteria^{39,40,41} to better account for small changes in serum creatinine not captured by RIFLE. The revision indicates that AKI can be diagnosed with a period of oliguria of at least 6 hours or a serum creatinine increase of ≥ 0.3 mg/dL from baseline. However, diagnostic increments of serum creatinine should occur during a period of no more than 48 hours, compared to 7 days for the RIFLE criteria. AKIN criteria caution that adequate volume resuscitation should be ascertained and urinary tract obstruction ruled out prior to using urine output to identify AKI. Moreover, it should be noted that a change in urine flow is less helpful as a diagnostic criterion because of the high incidence of nonoliguric AKI.⁴² The KDIGO Clinical Practice Guidelines for AKI included a revision to the definition of AKI while retaining the AKIN staging criteria.⁴³ In the KDIGO definition, the time frame for an absolute increase in serum creatinine of ≥ 0.3 mg/dL is retained from the AKIN definition (48 hours), while the time frame for a $\geq 50\%$ increase in serum creatinine reverted to the 7 days originally included in the RIFLE criteria. All criteria mentioned above have the greatest utility in epidemiologic studies and in designing clinical studies in AKI. It is likely that they will eventually be revised or changed with the developing body of sensitive and specific biomarkers of renal tubular injury (Table 109-4).

DIAGNOSIS

AKI diagnosis in the ICU typically occurs in the context of another acute illness and can often be linked with a specific precipitating event, such as the development of sepsis, hemodynamic compromise, cardiac surgery, radiocontrast exposure, or nephrotoxic medications. The aforementioned diagnostic criteria can be used to establish the diagnosis utilizing serum determinations of creatinine and urea. However, patients who receive aggressive volume resuscitation will have the rise in serum creatinine blunted due to a dilution in a larger volume of distribution.⁴⁴ Oliguria is not sensitive to renal dysfunction but may improve the diagnostic yield of AKI when added to creatinine.⁴⁵ An attempt should be made to establish whether the patient has AKI, CKD, or an episode of acute superimposed on chronic disease. In some situations, the presentation is less clear, the possibility of obstruction as a cause of AKI or acute-on-chronic kidney disease should be considered, and renal sonography may be of use. Often, patients present with AKI in the absence of obstruction or a clear prerenal cause. Urine microscopy using a quantitative evaluation of the urine sediment for renal tubular epithelial cells, renal tubular epithelial cell casts, and granular casts has recently been shown to differentiate prerenal AKI from ATN and also provide prognostic information.^{46,47} Urinary microscopy occasionally suggests glomerular pathologic changes, with hematuria, proteinuria, fragmented red cells, red cell casts, white cell casts, granular casts, or a combination of these factors.¹² Urine biochemical analysis is of limited use in determining the etiology of AKI,

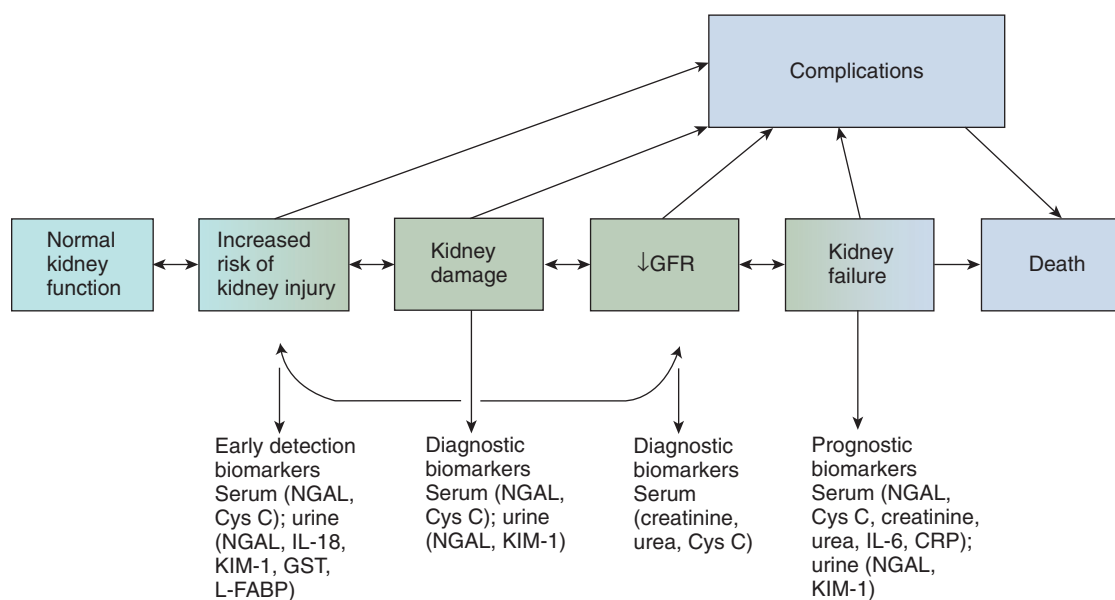

FIGURE 109-2 ■ Evolution of acute kidney injury and novel biomarkers. Injury begins before the excretory function is lost (i.e., decreased GFR) and in some cases can be detected by the measurements of biomarkers. Such biomarkers can also be used for diagnostic and prognostic assessment. CRP, C reactive protein; Cys C, cystatin C; GFR, glomerular filtration rate; GST, glutathione-S-transferase; IL-18, interleukin-18; IL-6, interleukin-6; KIM-1, kidney injury molecule 1; L-FABP, liver fatty-acid-binding protein; NGAL, neutrophil gelatinase-associated lipocalin. (From Bellomo R, Kellum JA, Ronco C. Acute kidney injury. *Lancet* 2012;380(9843):756-66.)

especially in sepsis. Measurement of the fractional excretion of sodium or urea has not been consistently shown to have a clear correlation with histopathologic findings in systematic reviews.^{48,49}

■ NOVEL BIOMARKERS

Several novel biomarkers are currently being developed (Fig. 109-2). In patients with AKI, the concentrations of some of these biomarkers seem to change earlier than the serum creatinine concentrations and thereby may allow early intervention. In addition, biomarkers appear capable of differentiating etiologies of renal injury.¹² For example,

cystatin C concentrations seem to reflect changes in GFR,^{50,51} whereas concentrations of neutrophil gelatinase-associated lipocalin are related to tubular stress or injury.^{52,53} Moreover, these biomarkers seem to change with treatment or recovery, suggesting that they can be used to monitor interventions.⁵⁴ Several other biomarkers are also under investigation, such as urinary interleukin (IL)-18, urinary liver-type fatty acid-binding protein,⁵⁶ and kidney injury molecule 1 (KIM-1).⁵⁷

Further studies are required to establish any of these or other potential biomarkers as practical diagnostic tools in the early clinical diagnosis of AKI. Such tools may facilitate timely and aggressive therapeutic interventions.

TREATMENT

In light of its dismal outcome, it is imperative that therapies to prevent or ameliorate AKI be developed. The fundamental principle of prevention of AKI is to treat the cause. If prerenal factors contribute, they should be identified and intravascular volume maintained or rapidly restored.

With the increasing use of contrast agents in diagnostic and therapeutic procedures, prevention of contrast-mediated nephropathy has been studied extensively. Intravenous fluids have long been used to prevent contrast nephropathy, but in patients with chronic renal insufficiency, the incidence is still high. Data suggest that low- or iso-osmolal rather than high-osmolal contrast agents are associated with a decreased risk of contrast-induced nephropathy. Since alkalization may protect against free radical injury, the possibility that sodium bicarbonate may be superior to isotonic saline has been examined in a number of randomized trials and meta-analyses. The majority of these studies suggest that both are equivalent or that sodium bicarbonate was better. However, a recent randomized trial comparing a prolonged infusion of isotonic saline (1 mL/kg/h for at least 12 hours prior to and after the contrast-associated procedure) with briefer infusions of isotonic bicarbonate (3 mL/kg for 1 hour prior to the procedure and 1 mL/kg/h for 6 hours after the procedure or 3 mL/kg over 20 minutes prior to the procedure plus oral sodium bicarbonate 500 mg per 10 kg) observed a lower rate of contrast nephropathy with isotonic saline.⁵⁸ N-Acetylcysteine (NAC) has been studied in contrast-induced nephropathy (CIN) prevention for its antioxidant and vasodilatory effects, with mixed results. In the largest study of ST-segment elevation myocardial infarction (STEMI) patients undergoing PCI examining NAC 1200 mg twice daily for 48 hours, NAC was shown to reduce oxidative stress but not the risk for CIN when compared with the placebo.⁵⁹ Two subsequent randomized clinical trials failed to show a difference in the incidence of CIN with NAC treatment.⁶⁰

There is growing interest in the use of statins for the prevention of CIN. Findings from the largest meta-analysis, including five single-center randomized controlled trials (RCTs) and three multicenter RCTs, support the use of short-term statin therapy for prevention of CIN.⁶¹

Currently, our recommendation for preventing contrast nephropathy in high-risk patients (Table 109-5) is to seek an alternative procedure not requiring contrast whenever possible. If that is not feasible, high osmolal contrast should not be used. Adequate hydration with isotonic sodium chloride or bicarbonate should be performed. Despite conflicting evidence, the oral administration of 1200 mg acetylcysteine twice daily the day before and day of the procedure should be considered (given its tolerability and relatively low cost).

Dopamine has long been used to treat AKI. The renal effects of dopamine include an increase in GFR, as well as sodium and water excretion. Clinically, the first response is an increase in diuresis.⁶⁴ These responses occur in patients with normal renal function, but it is unknown whether they are also seen in patients with AKI. In patients with early renal dysfunction (serum creatinine >1.8 mg/dL or urine output <0.5 mL/kg/h), dopamine did not alter peak serum creatinine or the need for renal replacement therapy (RRT).⁶⁵ This was confirmed in a meta-analysis to determine whether the progression of AKI, need for RRT, or mortality was affected by dopamine.⁶⁶

Aside from the lack of efficacy in AKI, dopamine has deleterious side effects. It hastened the onset of gut ischemia in an experimental model⁶⁷ and clinically worsened contrast nephropathy.⁶⁸ In cardiac surgery

patients, dopamine was independently associated with an increased risk of postoperative atrial fibrillation.⁶⁹ Higher doses may increase mortality,⁷⁰ perhaps by worsening myocardial ischemia.⁷¹ Therefore, low-dose dopamine currently has no role in the treatment or prevention of AKI.

Diuretics are also frequently used in patients with AKI, especially in an attempt to convert oliguric into nonoliguric AKI, given the improved prognosis of the latter.⁷²⁻⁷⁴ Loop diuretics, most commonly furosemide, inhibit Na⁺/K⁺-ATPase in the thick ascending loop of Henle and therefore decrease the active reabsorption of sodium. Theoretically, this has some potential benefits, such as decreasing energy expenditure and increasing the flow rate to flush out tubular casts. Ho et al. recently conducted a comprehensive systematic review of the use of furosemide in AKI.⁷⁵ They have shown that furosemide is not associated with any significant clinical benefits in the prevention or treatment of ARF in adults. High doses may be associated with an increased risk of ototoxicity. Although the use of loop diuretics in early or established AKI facilitates management of fluid overload, hyperkalemia, and hypercalcemia, any active role in the prevention or amelioration of the AKI course remains unproven. Any putative role in the prevention or amelioration of the AKI course remains unproven. Therefore, if diuretics are employed, care must be taken to avoid delaying the initiation of dialysis if clinically necessary.

Atrial natriuretic peptide (ANP) is a hormone secreted by the cardiac atria that increases GFR and glomerular filtration pressure by dilating the afferent arteriole and constricting the efferent arteriole.⁷⁶ It also decreases tubular reabsorption of sodium and chloride,⁷⁷ redistributes medullary blood flow,⁷⁸ disrupts tubuloglomerular feedback,⁷⁹ and reverses endothelin-induced vasoconstriction.⁸⁰ Sezi et al. studied the postoperative changes in serum creatinine and the need for dialysis 1 year following surgery among 285 patients with CKD not yet on dialysis who were undergoing on-pump coronary artery bypass grafting. Patients who received ANP had a significantly smaller postoperative increase in serum creatinine, compared to the controls. In the early postoperative period and 1 year later, fewer patients in the ANP group required dialysis.

Fenoldopam, a dopamine receptor-1 agonist, has been studied for the prevention of AKI following cardiac surgery and in other patients, including those with sepsis. A randomized controlled trial on patients admitted to intensive care units with early AKI following cardiac surgery found that fenoldopam infusion, compared with placebo, did not reduce the need for renal replacement therapy or the risk of 30-day mortality but was associated with an increased rate of hypotension.⁸¹

HEMODYNAMIC MANAGEMENT

Intravascular volume is critical in maintaining hemodynamic stability, tissue oxygenation, and organ function.⁸² In a study by Rivers and associates, it was shown that early goal-directed therapy (EGDT) based on optimizing the mixed control venous oxygen saturation in the first 6 hours resulted in decreased mortality in septic patients.⁸³ However, studies have shown increased mortality in patients with positive fluid balance and acute respiratory distress syndrome (ARDS).⁸⁸⁻⁹⁰

With ARDS and prolonged ventilatory support, a very high mortality occurs, particularly in the presence of renal and multiorgan failure. Bouchard and colleagues have reported results of a prospective multicenter observational study of 618 patients that aimed to determine whether fluid overload (>10% increase in body weight) in critically ill patients with AKI is associated with increased mortality. After an adjustment for severity of illness, the study found that fluid overload was independently associated with mortality in AKI patients who did and did not receive dialysis therapy.⁹² A randomized study demonstrated that pulmonary function in critically ill patients was worse in those treated with a liberal fluid management strategy (to achieve a mean central venous pressure [CVP] of ~12 mm Hg) than in those who were treated with a conservative strategy (to achieve a mean CVP ~ 8 mm Hg).⁹³ Moreover, fewer patients in the conservative strategy group required dialysis than in the liberal strategy group. Several pediatric studies, comprising more than 400 children, have demonstrated an association between worsening fluid overload (higher than 10% to

TABLE 109-5 Risk Factors for Contrast Nephropathy

20%) and mortality.⁹⁴⁻⁹⁶ Among patients who developed AKI within 2 days in the NIH ARDS Network FACTT trial, the positive fluid balance was associated with lower 60-day survival in a post hoc analysis.⁹⁷ The RENAL study also demonstrated that a negative fluid balance in patients requiring RRT was associated with increased survival and shorter ICU and hospital stay.⁹⁸ Thus, there are reasons to believe that fluid overload is not just a marker but rather a pathologic factor for high mortality of critically ill patients with AKI. Prospective randomized clinical trials will be needed to confirm this possibility. Until such studies are available, however, we recommend the avoidance of fluid overload in patients with AKI on the basis of knowledge of body weight changes and cumulative fluid balance.⁹⁹

Fluid management in critical illness is aimed at improving organ perfusion. When volume replacement is indicated, both crystalloids (e.g., isotonic saline and Ringer's lactate) and colloid-containing solutions (e.g., albumin solution and colloidal substances) have been used to replace the extracellular fluid deficit. Crystalloids are the most common form of volume replacement, but their effect on plasma volume is limited. Each liter of fluid administered increases plasma volume 200 mL, but the intravascular half-life is only 20 to 30 minutes.⁸²

Colloidal substances, such as albumin, dextran, and hydroxyethyl starches (HESs), because they are macromolecules, are better retained within the intravascular space and have a greater effect on plasma volume. Albumin has been used for decades, but it is expensive and may cause an increase in mortality, according to the Cochrane Injuries Group.¹⁰⁰ Nevertheless, a randomized controlled trial was conducted to compare human albumin with crystalloid in ICU patients (Saline versus Albumin Fluid Evaluation [SAFE] study). This study found that albumin is safe, albeit no more effective than saline for fluid resuscitation. The SAFE study also demonstrated no difference in renal outcomes based on the duration of RRT.¹⁰¹ Dextran cannot be recommended for plasma volume expansion because of serious side effects, such as coagulation abnormalities and increased development of AKI.

HESs are polymers of amylopectin that vary in molecular weight and the number of substitutions of hydroxyethyl groups. As molecular weight and the number of substitutions increase, side effects also increase. Two recent randomized controlled trials using newer HES with lower molecular weights and less substitution showed a neutral or negative effect on mortality, as well as an increased need for RRT.^{102,103} The CHEST trial compared fluid resuscitation with 6% HES 130/0.4 versus 0.9% saline. This randomized controlled trial showed no significant mortality difference at 90 days between the two groups but did demonstrate an increased need for RRT in the HES group, as well as greater numbers of treatment-related adverse events. A meta-analysis indicated similar tendencies of increased RRT with the absence of survival benefit.¹⁰⁴ Therefore, synthetic colloids should be avoided in patients with AKI or at risk of developing AKI, including most patients in the ICU and operative settings.

Although crystalloids remain the first choice for fluid therapy in critically ill patients, there may be differences in renal outcomes among them. A recent study demonstrated decreased renal artery flow and cortical perfusion in subjects who received 0.9% saline compared to a balanced solution (Plasma-Lyte 148).¹⁰⁵ An Australian prospective study found lower increases in creatinine, lower incidence of RIFLE "injury," and a diminished need for RRT in ICU patients treated with a chloride-restrictive approach as opposed to a chloride-liberal strategy.¹⁰⁶ These results will need to be confirmed with other studies. In sepsis and septic shock, hypotension may occur despite normal or increased cardiac output.¹⁰⁷

Sepsis-associated hypotension is often unresponsive to fluid and requires the administration of vasopressor agents. Since such agents cause vasoconstriction, there has been concern about their use in AKI. A large randomized trial comparing dopamine to norepinephrine as initial vasopressors in patients with septic shock showed no significant differences between groups with regard to renal function or mortality through norepinephrine, was associated with less tachycardia in the initial hours following treatment, and was superior concerning survival in cardiogenic shock patients.¹⁰⁸

Vasopressin is a hormone secreted by the posterior pituitary gland and increases systemic vascular resistance by activating V_{1a} receptors on vascular smooth muscle. During septic shock, there is a biphasic response with early high levels of endogenous vasopressin followed by a subsequent decrease.¹⁰⁹ The renal effects of vasopressin are complex and involve the interplay between V_1 and V_2 receptors that regulate the antidiuretic function of vasopressin.¹⁰⁹ In clinical trials, vasopressin increases blood pressure and enhances diuresis in hypotensive oliguric patients with sepsis but has not yet been proven to enhance survival nor been shown to prevent or ameliorate AKI.¹¹⁰

It has been proposed that tight glycemic control can reduce the incidence and severity of AKI in critical patients. However, recent studies have highlighted significant concerns regarding the effectiveness and safety of using intensive insulin therapy with tight glycemic control to prevent or ameliorate morbidity and mortality of AKI or other forms of organ injury. The international Normoglycemia in Intensive Care Evaluation and Survival Using Glucose Algorithm Regulation (NICE-SUGAR) study enrolled over 6000 patients and set out to determine the risk/benefit of tight glycemic control in critically ill patients.¹¹¹ It showed that in contrast to conventional insulin therapy, intensive glucose control increased mortality among these patients. A blood glucose target of ≤ 180 mg/dL resulted in a lower mortality than a target of 81 to 108 mg/dL. Therefore, it may be prudent to use conventional insulin therapy in ICU patients at risk of AKI to target plasma glucose of less than 150 mg/dL to avoid hypoglycemia.

NUTRITIONAL SUPPORT

Nutritional support in patients with AKI does not differ significantly from that of critically ill patients. AKI affects water, electrolyte, and acid-base balance, but it also induces changes in protein, carbohydrate, and lipid metabolism.¹¹² Patients with AKI should be supplemented with 20 to 30 kcal/kg body weight per day. Even in hypermetabolic states such as sepsis, energy expenditure is rarely greater than 130% of the calculated basic energy expenditure. In a randomized trial in AKI patients, comparing 30 and 40 kcal/kg/d energy provision, the higher energy prescription did not induce a more positive nitrogen balance but was associated with a higher incidence of hyperglycemia and hypertriglyceridemia and a more positive fluid balance.¹¹³ Therefore, supplementation should not exceed 30 kcal/kg/d. In the past, protein restriction was employed in AKI patients to control uremia, but this is likely to be detrimental to the patient and results in a profoundly negative nitrogen balance.¹¹⁴ With the advent of continuous modalities of RRT, it is possible to adequately supplement protein and control uremia. Therefore, some authors recommend aggressive protein replacement at 2.5 g/kg/d, as opposed to the standard 1 to 1.5 g/kg/d.¹¹⁴ However, no compelling data are currently available concerning the efficacy and safety of such high protein intakes. Also, it is important to realize that hypercatabolism cannot be simply overcome by increasing protein or amino acid intake. We suggest administering 0.8 to 1.2 g/kg/d of protein in patients with AKI without the need for dialysis, and 1 to 1.5 g/kg/d in patients with AKI on RRT.

INDICATIONS FOR NEPHROLOGY CONSULTATION

Currently, there are wide variations in the timing of nephrology consultation in patients with AKI. Some physicians prefer to consult at the first elevation in serum creatinine, whereas others wait until RRT is needed. In a study evaluating the effect of nephrology consultation on patient outcome, Mehta and associates found that a delay in nephrology consultation (>48 hours after ICU admission with AKI) led to higher mortality.¹¹⁵ In this study, patients with delayed consultation had a lower serum creatinine concentration and higher urine output but a greater extent of organ failure and higher total body water content. In the multivariate analysis, delayed consultation was no longer significant, but a trend remained toward this being a factor in the outcome. A study by Ponce et al. explored the associations between

nephrology consultation, ICU stay, and in-ICU mortality in 148 ICU patients with AKI at a Brazilian teaching hospital. Multivariable logistic regression showed that delayed consultation was associated with increased ICU mortality.¹¹⁶ Why would early consultation affect mortality? This association could result from a delayed recognition of renal failure. Higher total body water content likely leads to tissue edema and organ dysfunction (i.e., pulmonary edema). Therefore, in ICU patients, early recognition of AKI and its appropriate management may lead to better outcomes.

RENAL REPLACEMENT THERAPY

Indications

As mentioned previously, up to a third of patients in the ICU develop AKI. Of those, 30% to 70% require RRT.^{25,26,27} Many practitioners delay initiating RRT as long as possible because of concerns that dialysis may delay the recovery of renal function.^{117,118} The optimal timing of initiation of dialysis is not defined. There is little disagreement in commencing dialysis in the presence of life-threatening conditions, such as diuretic-resistant volume overload, severe hyperkalemia, acidosis, azotemia, or overt symptoms and signs of uremia (e.g., encephalopathy and pericarditis). Medical treatment approaches for hyperkalemia result in intracellular shifts of potassium. When intermittent hemodialysis is used to correct hyperkalemia after such measures have been utilized, dialytic potassium removal will be reduced, and higher serum levels of postdialysis potassium can occur.¹¹⁹ Metabolic acidosis is common in severe AKI but can be corrected with bicarbonate and rarely requires urgent dialysis if not accompanied by volume overload or uremia.¹²⁰ Some poisons, drug overdoses, and toxic compounds can contribute to acid-base disturbances and AKI. In such cases, dialysis can be supportive and facilitate the removal of these substances and their metabolites. In acute salicylate poisoning, RRT is indicated when the serum concentration is above 100 mg/dL and the patient exhibits altered mental status, pulmonary or cerebral edema, renal impairment, fluid overload that prevents the administration of sodium bicarbonate, or clinical deterioration despite aggressive and appropriate supportive care.¹²¹ Ethylene glycol and methanol poisoning are important causes of anion-gap metabolic acidosis. Dialysis treatment has been shown to reduce the development of subsequent AKI and organ dysfunction.¹²² Metformin-associated lactic acidosis may be an indication for dialysis, especially in critically ill patients at risk of death. In particular, such patients demonstrate a low pH (<6.9), as well as high serum lactate and metformin concentrations.¹²³

The level of azotemia at which RRT should begin is unknown. Several early retrospective studies that used blood urea or blood urea nitrogen (BUN) suggest that early initiation of RRT results in survival improvements.¹²⁴ More recent studies have continued to focus on BUN as a marker for starting dialysis. Serum concentrations of BUN and creatinine are recognized to be inherently subject to a multitude of factors other than kidney function, such as catabolic rate, volume status, age, race, and muscle mass. Single-center observational studies that were restricted to AKI after trauma¹²⁵ and coronary artery bypass surgery^{126,127} suggested a benefit to dialysis initiation at lower BUN concentrations. A prospective multicenter observational study analyzed dialysis initiation, as inferred by BUN concentration in 243 geographically and ethnically diverse patients.¹²⁸ Survival rates were slightly lower for patients who started dialysis at higher BUN concentrations, despite a lower burden of organ system failure. In a prospective multicenter observational trial study conducted at 54 ICUs in 23 countries, the timing of RRT was stratified into “early” or “late” by median urea at the time RRT was initiated and also categorized temporally from ICU admission into early (<2 days), delayed (2–5 days), or late (>5 days).¹²⁹ Timing by serum urea showed no significant difference in mortality. However, when the timing was analyzed in relation to ICU admission, late RRT (this may also be late AKI) was associated with greater overall mortality and covariate-adjusted mortality. Late RRT was also associated with a longer duration of RRT

TABLE 109-6

Potential Indications for Renal Replacement Therapy in the ICU

| |
|---|
| Nonobstructive oliguria (urine output <200 mL/12 h) or anuria |
| Severe acidemia |
| Azotemia (blood urea nitrogen >80 mg/dL) |
| Hyperkalemia (K^+ >6.5 mmol/L)* |
| Uremia (encephalopathy, pericarditis, neuropathy, myopathy) |
| Severe dysnatremia (Na^+ >160 or <115 mmol/L) |
| Clinically significant organ edema (especially lung) |
| Drug overdose with dialyzable toxin |
| Coagulopathy requiring large amounts of blood products in a patient at risk for acute respiratory distress syndrome |
| NOTE: Any one of these indications is sufficient to consider initiating renal replacement therapy. Two of these indications make renal replacement therapy desirable. |

*Intermittent hemodialysis removes K^+ more efficiently than continuous modalities.

and stay in the hospital, and greater dialysis dependence. Vaara et al. recently published a study addressing the question of timing by defining a set of classic indications for RRT in AKI, including hyperkalemia, acidosis, and volume overload.¹³⁰ Using data from the FINNAKI study, a prospective, multicenter ICU cohort study in which 33.7% of 2901 patients developed AKI, the authors identified four groups of individuals: (1) those who received RRT within 12 hours of developing conventional indications; (2) those who received RRT >12 hours after developing conventional indications; (3) those who received RRT before conventional indications; and (4) a propensity-matched group of individuals who never received RRT. Regarding the 90-day mortality rate, preemptive RRT appeared to be the most effective treatment strategy (the mortality rate was 26.9% compared with 48.5% among those who received RRT for conventional indications). There are ongoing trials of dialysis timing in AKI. Until the results of these are available, it would be prudent not to base a dialysis initiation decision on single BUN and creatinine thresholds but rather on the broader clinical context and trends of laboratory tests. Finally, it is important to consider the volume status when deciding the time for initiating RRT because volume overload, as previously discussed, appears to be an important factor associated with mortality in AKI. Table 109-6 depicts accepted indications for initiating RRT in the ICU.

Adequate Dialysis Dosing

In chronic hemodialysis patients, adequacy of dialysis is primarily determined by the level of small-solute (urea) clearance. This is determined by the Kt/V formula, where K is the dialysis membrane clearance of urea, t is the time on dialysis, and V is the volume of distribution of urea, which is equal to the total body water content. In chronic hemodialysis, a Kt/V of 1.2–1.4 per session is considered adequate.¹³¹ As seen from the formula, one can increase the time on dialysis or increase the dialyzer clearance to enhance urea clearance. Dialyzer clearance depends on blood flow and dialysate flow rates, as well as the inherent properties of the membrane.

In the United States, intermittent hemodialysis and continuous RRT are the most commonly used modalities of RRT, with sustained low-efficiency dialysis and other “hybrid” treatments used in fewer than 10% of patients. Intermittent hemodialysis is most commonly provided on a thrice-weekly or every-other-day schedule.¹³² Concerning intermittent modalities, there is currently no standard Kt/V for adequate dialysis in AKI, but it has been suggested that a higher target Kt/V confers better patient outcomes. Schiffil and colleagues studied 160 patients with AKI who were divided into two groups: (1) a group that received daily hemodialysis; and (2) a group that received alternate-day hemodialysis. It was found that daily hemodialysis resulted in less

TABLE 109-7 Practical Comparison of Acute Renal Replacement Therapy Modalities

| | INTERMITTENT HEMODIALYSIS | SUSTAINED LOW-EFFICIENCY DIALYSIS | CONTINUOUS RENAL REPLACEMENT THERAPY |
|---------------------------|------------------------------|--------------------------------------|---|
| Session duration (h) | 3-5 | 8-12 | 24 |
| Blood flow, mL/min | 300-400 | 200-300 | 100-200 |
| Dialysate flow, mL/min | 500-800 | 200-350 | 25-40 |
| Anticoagulant requirement | Heparin or none | Heparin or none | Heparin or regional citrate |

Data from Fieghen H, Wald R, Jaber BL. Renal replacement therapy for acute kidney injury. *Nephron Clin Pract* 2009;112:222-9.

hypotension, sepsis, gastrointestinal bleeding, and respiratory failure, as well as a significant decrease in mortality.¹³³ This study has been criticized because the Kt/V delivered to the alternate-day group was only 0.94, which is significantly less than the prescribed dose of 1.2. Therefore, the results could be explained by the fact that the alternate-day group received inadequate dialysis. In contrast, the VA/NIH Acute Renal Failure Trial Network Study (ATN study) did not find a benefit for a more intensive dosing strategy for RRT.¹³⁴ This study compared intermittent hemodialysis (hemodynamically stable patients) or sustained low-efficiency dialysis (hemodynamically unstable patients) performed three (less intensive) versus six (more intensive) times a week in 563 critically ill patients with AKI and the failure of at least one nonrenal organ or sepsis. The prescribed Kt/V per session was 1.2 to 1.4, and the actual delivered mean dose was 1.3 in the less intensive arm. The 60-day mortality rate and percentage of patients recovering renal function were similar in both groups. The Hannover Dialysis Outcomes study was a prospective randomized, parallel group study that used intensified extended dialysis (dosed to maintain plasma urea levels < 90 mg/dL) versus standard dialysis (dosed to maintain plasma urea levels between 120 and 150 mg/dL) on 14- and 28-day mortality and renal function.¹³⁵ The mortality and frequency of renal function recovery were similar between the two groups. Based on these two well-designed and performed clinical trials, it appears that increasing urea target clearances do not improve mortality or rates of renal recovery. Therefore, at least the smaller dose used in these trials should be pursued, with monitoring of the delivered dose of therapy to ascertain a minimum delivery of Kt/V of 1.2 per treatment when using extended or intermittent RRT in AKI patients. The significant difference between the prescribed and delivered dialysis dose was studied by Evanson and coworkers, who found that the prescribed dose was a Kt/V of 1.25, whereas the dose delivered was only 1.04.¹³⁶ These authors found that the most significant factor predicting the actual delivered dose was the patient's predialysis weight. It follows that a higher weight in critically ill patients represents higher total body water and, therefore, a larger volume of urea distribution. This would be expected to decrease the Kt/V if it were not accounted for in the prescription of dialysis.

CRRT has been advocated in patients with AKI because of its ability to remove solute more efficiently¹³⁷ and provide hemodynamic stability, but the optimal dosing in CRRT is not known. CRRT depends on convection, not diffusion, for solute clearance, meaning that there is no dialysate involved and the solute is removed with water during ultrafiltration. In the aforementioned VA/ATN study, 201 patients received predilutional continuous venovenous hemodiafiltration (CVVHDF) in the less intensive arm (mean delivered effluent of 22 mL/kg/min) and 179 in the intensive therapy group (mean delivered effluent of 36 mL/kg/min).¹³⁴ A higher dose of CRRT did not influence mortality or renal recovery. The Randomized Evaluation of Normal versus Augmented Level of RRT (RENAL) study was conducted at 35 centers throughout Australia and New Zealand.¹³⁹ It compared the effects of postdilutional CVVHDF doses of 25 and 40 mL/kg/h on the 24-day and 90-day mortality rates of 1508 critically ill AKI patients. Treatment with a higher intensity regimen did not reduce the mortality at 90 days. In conclusion, the results of these two recent

well-designed and executed large clinical trials (ATN and RENAL) did not show any benefit of higher CRRT doses for critically ill AKI patients beyond a threshold necessary to optimize clinical outcome. Therefore, when using CRRT for treating such patients, a minimum dose to be targeted may be the minimal efficient one used in these trials: 20 to 25 mL/kg/h.

Dialysis Modality

When RRT is indicated in the ICU for severe AKI, physicians must choose between intermittent techniques (e.g., traditional intermittent hemodialysis [IHD; used in ESRD]), slow low-efficiency dialysis (SLED), or continuous therapies (e.g., CVVH and peritoneal dialysis [PD]) (Table 109-7). SLED is performed by utilizing dialysis machines to deliver a slow dialysate flow for periods ranging from 8 to 12 hours per day. Advantages of this technique include high hemodynamic tolerance, excellent solute-removal capability, and the capacity to be instituted using regular hemodialysis machines without acquiring new equipment. Availability and expertise with the technique, as well as the hemodynamic status of the patient, are typical determining factors for modality choice for AKI.

RRT is required in severe AKI to remove uremic toxins and maintain fluid, electrolyte, and acid-base balance. CRRT and IHD are effective therapies that may be utilized and exchanged according to the hemodynamic status or coagulation problems of the patient. The effect of these modalities on patient outcomes has been evaluated. Lins et al. performed a multicenter, randomized controlled trial to study the effect of intermittent versus continuous dialysis modalities for the treatment of 316 AKI patients who were admitted to the ICU.¹⁴⁰ They demonstrated that ICU stay, hospitalization, mortality, and renal recovery rates were not different between the groups. Moreover, two systematic reviews that collectively analyzed 45 studies found that outcomes were similar in critically ill AKI patients (stratified according to severity of illness) with CRRT and IHD for hemodynamically stable patients for the relative risk of death, ICU mortality, in-hospital mortality, length of hospitalization, and requirement for chronic dialysis or renal recovery in survivors.^{141,142}

Control of both uremia and volume is the major goal of RRT in AKI. A few studies have suggested that CRRT has advantages over intermittent therapies, including hemodynamic stability, improved survival, greater likelihood of renal recovery,^{141,143,144} and better fluid balance.¹⁴⁵ IHD is complicated by hypotension in 20% to 30% of patients.¹⁴⁶ In hemodynamically unstable patients, this can significantly limit therapy and delay the recovery of renal function. Therefore, some clinicians favor initiating CRRT for hemodynamically unstable patients with AKI, but this has not been supported by a prospective randomized trial¹⁴⁷ or systematic reviews.^{141,142} Moreover, Bagshaw et al. performed a systematic review and meta-analysis of nine randomized trials and concluded that it is impossible to make definitive recommendations about the initial RRT modality because of numerous issues related to study design, conduct, and quality of these trials.¹⁴⁸ The main disadvantage of CRRT is the need for prolonged anticoagulation. SLED is gaining popularity as an intermittent modality in ICUs. Two RCTs that

compared SLED with CVVH or CVVHD^{149,150} found similar outcomes concerning hemodynamic stability and uremic clearance. Furthermore, a decreased anticoagulation requirement was reported for SLED.¹⁵⁰ Based on such evidence, all of these modalities should be viewed as complementary. CRRT or SLED may be utilized for severe AKI with hemodynamic instability and transitioned to IHD once stability is attained. Peritoneal dialysis is an alternative modality for AKI in which vascular access may be difficult, in conditions where anticoagulation may be problematic, in under-resourced regions, or following large disasters with mass casualties.¹⁵¹ A prospective randomized study of daily IHD versus PD in 120 AKI patients showed no difference in survival or recovery of renal function.¹⁵² These results contrast with a previous study that showed decreased survival associated with PD in comparison to CVVH¹⁵³ and suggest that PD remains an acceptable option to CRRT when dosed appropriately.

In certain situations, CRRT is preferable to IHD, including in patients with or at risk for increased intracranial pressure. Studies have shown that CRRT prevents the increase in intracranial pressure associated with intermittent RRT and may be preferred in patients with acute brain injury or fulminant hepatic failure.^{154,155} The use of CRRT in patients with severe sepsis or septic shock has also received much attention. Sepsis is associated with hemodynamic instability, making CRRT an attractive option. It has been shown that CRRT has beneficial effects on the hemodynamics in animal models of sepsis.¹⁵⁶ This is thought to be secondary to the removal of inflammatory cytokines by both convective and adsorptive measures. Hemofiltration membranes allow the ultrafiltration of mid-molecular-weight molecules, such as cytokines. Furthermore, the continuous blood-membrane contact allows the membrane to adsorb an increased number of mediators. There is some evidence that hemofiltration may provide some benefit in sepsis and AKI.^{157,158}

Despite the potential hemodynamic advantage over IHD, CRRT has some disadvantages as well. With CRRT, there is a need for continuous anticoagulation to prevent clotting of the filter. This can be done with low-dose systemic heparin; however, there remains the risk of bleeding or heparin-induced thrombocytopenia. Regional citrate anticoagulation (RCA) is used in some centers. A number of recent clinical studies have shown advantages of RCA compared with heparin regarding prolonged circuit life, reduced incidence of hemorrhagic complications, and lower transfusion needs.¹⁵⁹ On the basis of these data, the KDIGO Clinical Practice Guidelines for AKI recommend the use of RCA as the preferred anticoagulation modality for CRRT in patients without contraindications for citrate, even in the absence of an increased bleeding risk or deranged coagulation.¹⁶⁰

Dialysis Buffer

In determining the adequacy of dialysis, factors other than solute clearance must be considered. One goal of RRT is to maintain a normal acid-base balance in patients with AKI to prevent the complications of acidemia concerning cardiovascular performance, hepatic metabolism, and hormonal response. To maintain a normal pH, the dialysate must contain a buffer. Bicarbonate-based solutions are currently the buffer of choice and are available in separate solutions that are mixed just before use. When regional citrate anticoagulation is utilized, the buffer may need to be decreased or deleted from the dialysate. In this setting, the citrate infusion provides an alkali load and may result in the development of metabolic alkalosis.

Medication Dosing

During AKI, drugs normally eliminated by the kidney exhibit a markedly decreased clearance. As the physiochemical characteristics of the drugs affect the removal by dialysis and hemofiltration, the amount of the drug removed during these procedures may be sufficient to require supplemental dosing. For patients on hemodialysis, a supplemental dose of the drug is most commonly administered at the completion of

the dialysis session.¹⁶² Drug clearance with CVVH is through convective transport and approximates the unbound drug concentration in plasma multiplied by the ultrafiltration rate.¹⁶³ Drugs with molecular weights of less than 500 D are readily removed by either conventional hemodialysis or CVVH, but those with higher weights of 1000 to 5000 D are eliminated more efficiently by CVVH because of the use of high-flux membranes that allow the passage of larger molecules.

The volume of distribution greatly impacts the clearance of a drug, in that drugs with large volumes of distribution are likely to be bound to a greater extent in the tissues. In this setting, only a small amount has access to the vasculature at any time. For such drugs, clearance with CVVH is greater than with intermittent therapies because of the continuous nature of the clearance.¹⁶⁴ The extent of protein binding of a drug is important because the protein-drug complex has a molecular weight greater than 50,000 D. At this size, neither intermittent nor continuous therapies will efficiently remove the drug. However, the extent of protein binding is dependent on pH, uremia, concentration of free fatty acids, heparin therapy, and relative concentrations of drug and protein.¹⁶⁵ In critically ill patients, serum albumin is often decreased, thereby making more drug available for clearance during RRT. Because of the potential medication toxicities, as well as the need to maintain therapeutic levels of multiple medications, it is important to consider and adjust dosing during AKI and with RRT. Dosages of medications must be adjusted for the type of RRT, as well as for the specific characteristics of the drug.

CONCLUSION

Despite extensive clinical experience and improvements in supportive care, the mortality rate of critically ill patients with AKI remains high. Table 109-8 summarizes current recommendations for the care of patients with AKI. These recommendations are based on evidence from clinical trials as well as clinical judgment.

TABLE 109-8

Recommendations for the Evaluation and Treatment of Acute Kidney Injury

- Evaluate patient for AKI when serum creatinine increases by >0.3 mg/dL.
- Exclude prerenal causes (e.g., volume depletion, CHF, cirrhosis, NSAIDs, ACE inhibitors).
- Exclude postrenal causes with renal ultrasonography and postvoid residual.
- Review urine sediment (muddy brown casts, ATN; RBC casts, glomerulonephritis or vasculitis; pyuria, acute interstitial nephritis; bland sediment, prerenal or postrenal azotemia).
- Evaluate urine electrolytes in the absence of diuretics.
- After exclusion of pre- and postrenal azotemia and examination of the urine sediment and electrolytes, notify a nephrologist when serum creatinine is >2 mg/dL.
- Note the projected need for dialysis: oliguric ATN (urine volume <400 mL/24 h), 60%-70% of patients; nonoliguric ATN (urine volume >400 mL/24 h), 30%-40% of patients.
- Avoid excessive fluid resuscitation leading to pseudo-ARDS, ventilator support, and multiorgan complications.
- Avoid hypotension as generally there is no need to treat hypertension aggressively in the absence of a hypertensive crisis.
- Maintain fluid balance and treat hyperkalemia; do not use "renal-dose" dopamine.
- Review active medications for necessary dose adjustments.
- When indicated, use enteral rather than parenteral alimentation.
- Discuss timing for initiation and mode of renal replacement with a nephrologist (intermittent versus continuous and use of circuit anticoagulation).

ACE, angiotensin-converting enzyme; ARDS, acute respiratory distress syndrome; AKI, acute renal failure; ATN, acute tubular necrosis; CHF, congestive heart failure; NSAIDs, nonsteroidal antiinflammatory drugs; RBC, red blood cell.

KEY POINTS**Prerenal Causes**

1. Prerenal azotemia accounts for about 70% of community-acquired acute kidney injury (AKI) and 40% of hospital-acquired AKI.
2. Since there is no cellular injury in prerenal azotemia, it is reversible with the correction of causative factors such as volume depletion, use of nonsteroidal antiinflammatory drugs, or congestive heart failure.
3. Prerenal azotemia is characterized by bland urine sediment and a fractional excretion of sodium (FE_{Na}) less than 1%.

Postrenal Causes

1. Postrenal azotemia occurs when there is a bilateral obstruction to urine flow.
2. It is an uncommon cause of AKI in the ICU.
3. The evaluation includes renal ultrasonography and postvoid residual, which should be less than 50 mL.

Intrarenal Causes

1. These causes are defined according to the anatomic location of injury: glomerulus, tubule, interstitium, or vasculature.
2. The most common cause of intrinsic renal failure is acute tubular necrosis (ATN). Specific causes of ATN can be classified as hemodynamically mediated, such as in prolonged prerenal azotemia, hypotension, and sepsis toxic AKI; secondary to antibiotics, chemotherapeutic agents, and contrast media; or postsurgical AKI.
3. Differentiation from prerenal azotemia is suggested by the examination of urine sediment, which may demonstrate muddy brown casts, as well as an FE_{Na} greater than 1%. Novel biomarkers are promising in the early identification of kidney injury and may allow timely interventions able to improve outcome.

Epidemiology and Outcomes

1. AKI is a common complication of critical illness, occurring in up to a third of ICU patients.
2. In the majority of patients, it is multifactorial in nature with components of hypotension, sepsis, and drugs.
3. AKI mortality is as high as 50% of patients and part of the multiorgan failure.
4. The risk of developing AKI increases with age and in the presence of baseline chronic kidney disease (CKD), oliguria, and sepsis.
5. AKI can negatively affect the immune system and may eventually result in the development of CKD.

Definition of AKI

1. Blood urea nitrogen (BUN) and creatinine are the most common parameters measured, but they are not sensitive indicators of renal dysfunction in an acute setting. Ongoing research is evaluating early diagnostic roles of injury biomarkers.
2. The Acute Dialysis Quality Initiative (ADQI) has proposed a categorized definition of ARF called the RIFLE criteria, which were subsequently revised by the Acute Kidney Injury Network (AKIN) to better account for the small changes in serum creatinine not captured by RIFLE, and shorten the necessary time to establish the diagnosis.

3. AKIN has defined AKI as an increase in serum creatinine (Scr) from baseline to 48 hours: stage 1, an increase in Scr of 0.3 mg/dL or 150% to 200%; stage 2, an increase in Scr of 200% to 300%; stage 3, an increase in Scr of greater than 300% or greater than 4 mg/dL, or acute renal replacement therapy (RRT) commencement (irrespective of the preceding Scr increase or urine output). The latest Kidney Disease: Improving Global Outcomes criteria retained the AKIN but reverted the time frame for a $\geq 50\%$ increase in Scr to the 7 days originally included in the RIFLE criteria.

Treatment

1. To prevent contrast-induced AKI in patients at risk, hydration with isotonic saline or sodium bicarbonate is beneficial, with the possible addition of *N*-acetylcysteine before and after the procedure.
2. There is no role for dopamine in the treatment of AKI.
3. Diuretics have not been shown to prevent or ameliorate AKI. They can be used in the initial management of AKI to facilitate fluid balance and treat hyperkalemia or hypercalcemia, but their use should not delay commencing RRT when deemed clinically necessary.

Hemodynamic Management

1. Early goal-directed management may reverse adverse hemodynamics before tissue injury occurs and result in a better outcome.
2. Available evidence supports crystalloid use for resuscitating volume-depleted patients when the condition is not due to a hemorrhage.
3. When vasopressors are indicated, the effect on systemic hemodynamics outweighs the direct renal vasoconstriction.

Nutritional Support

1. Patients with AKI have increased protein catabolism due to insulin resistance.
2. Enteral nutrition is recommended.
3. Caloric supplementation should be 20 to 30 kcal/kg/d.
4. Protein restriction has no role in the management of AKI.

Indications for Nephrology Consultation

1. Early nephrology consultation may lead to improved outcome due to earlier recognition and interventions for AKI.

Renal Replacement Therapy

1. Dialysis initiation should not be based on a numeric BUN and creatinine threshold but rather on the broader clinical context (e.g., volume status and pericarditis), trends of laboratory tests, and metabolic indicators (e.g., refractory hyperkalemia and acidosis).
2. When using extended or intermittent dialysis in AKI, monitoring the delivered dose of therapy is recommended to ascertain the minimum delivered Kt/V of 1.2 per treatment.
3. With continuous venovenous hemofiltration, ultrafiltration rates of at least 20 mL/kg/h should be attained.

KEY POINTS—cont'd

Modality

1. Patients with delayed recovery from ATN often have fresh areas of necrosis on a renal biopsy. Dialysis-associated hypotension may exacerbate this condition.
2. Current evidence does not support the superiority of CRRT over intermittent therapies in the treatment of AKI.
3. RRT modalities should be viewed as complementary. CRRT or hybrid therapies may be utilized for severe AKI with hemodynamic instability and transitioned to IHD once stability is attained.
4. Drawbacks to the use of CRRT include an increase in nursing care, higher expense, and the need for continuous anticoagulation.
5. Regional citrate anticoagulation is the preferred anticoagulation modality for CRRT in patients without contraindications for citrate.

Dialysis Buffer

1. The bicarbonate-based buffer is currently the standard.
2. The buffer may need to be modified when regional citrate anticoagulation is utilized to avoid metabolic alkalosis.

Medication Dosing

1. In critical illnesses, both the volume of distribution and the extent of protein binding of the drugs change.
2. Owing to potential toxic effects, it is important to consider the degree of renal function when determining medication dosage.

ANNOTATED REFERENCES

Bagshaw SM, Uchino S, Bellomo R, et al. Timing of renal replacement therapy and clinical outcomes in critically ill patients with severe acute kidney injury. *J Crit Care* 2009;24:129-40.

This prospective multicenter observational study showed that the timing of RRT might exert an important influence on patient survival. Late RRT (days from admission) was associated with a longer duration of RRT, longer hospital stay, and higher dialysis dependence.

Chertow GM, Burdick E, Honour M, et al. Acute kidney injury, mortality, length of stay, and costs in hospitalized patients. *J Am Soc Nephrol* 2005;16:3365-70.

This is a large retrospective review that demonstrated that even small increases in serum creatinine are associated with significant increases in mortality, length of stay, and costs of hospitalized patients.

A patent urinary tract is necessary for optimal kidney function. Under normal circumstances, urine passes unimpeded from the renal pelvises to the tip of the urethra. Obstruction can occur anywhere along this pathway and may lead to both acute and progressive kidney parenchymal damage.

Several definitions may be encountered when considering urinary tract obstruction:

- *Obstructive uropathy* refers to any disorder that interferes with drainage of the urine. It may be acute or chronic and either partial or complete; the resulting symptom complex typically depends on both the acuity and severity.
- *Obstructive nephropathy* refers to cases in which obstructive uropathy causes a decline in renal function.
- *Hydronephrosis* refers to dilatation of the urinary collecting system, with renal parenchymal changes. Typically, however, the term is used to describe any dilatation of the urinary tract, regardless of renal parenchymal involvement. Hydronephrosis is usually, but not exclusively, seen in obstructive disorders. Nonobstructive pathogenesis of hydronephrosis includes vesicoureteral reflux or excessive flow through the collection system, such as with habitual water drinking or diabetes insipidus.

■ EPIDEMIOLOGY

Urinary tract obstruction is a common disorder. On autopsy, 3.1% of adults have hydronephrosis.¹ Data from the Healthcare Cost and Utilization Project's Nationwide Inpatient Sample (based on ICD-9 codes) indicate that 1.75% of all hospital discharges are complicated by either hydronephrosis or obstruction.² When hydronephrosis is excluded, urinary tract obstruction occurs in approximately 1% of hospital discharges.² Urinary tract obstruction accounts for approximately 10% of community-acquired acute kidney injury³⁻⁵ and is a factor in 2.6% of acute kidney injury cases in the intensive care setting.⁶

■ ETIOLOGY

Many disorders may lead to urinary tract obstruction. A useful classification is to first separate pathology arising from within the urinary tract itself (intrinsic obstruction) from those diseases that arise outside the urinary tract causing external compression of the system (extrinsic obstruction). This discussion will also consider upper (from the renal pelvis to the ureterovesicular junction [UVJ]) and lower (from the bladder to the urethra) urinary tract obstruction separately.

Intrinsic Obstruction

Intrinsic urinary tract obstruction may be due to pathology within the lumen (*intraluminal*) or within the walls of the collecting system (*intramural*).

Intraluminal Causes

Obstruction at the level of the renal tubules may be due to crystal-induced disease, uric acid nephropathy (as in tumor lysis syndrome), or cast nephropathy due to multiple myeloma. Crystal-induced nephropathy has been classically described with sulfadiazine, acyclovir, indinavir, triamterene, and methotrexate.⁷ Newer literature also implicates orlistat⁸ and ciprofloxacin.⁹

Nephrolithiasis is a common cause of upper urinary tract obstruction at the level of the ureter, with the size of the stone determining the likelihood of obstruction. Stones ≤ 2 mm, 3 mm, 4 to 6 mm, and >6 mm will pass spontaneously 97%, 86%, 50%, and 1% of the time, respectively.¹⁰ Typically the obstruction occurs at one of the three narrowest portions of the ureter: the ureteropelvic junction (UPJ), the UVJ, or at the point where the ureter crosses over the pelvic brim. Neoplasms, blood clots, and sloughed renal papillae are rarer causes of intraluminal obstruction at the level of the ureter.

The causes of intraluminal obstruction at the level of the bladder are similar to those affecting the ureter, with urolithiasis, blood clots, and neoplasms being the most common. Worldwide, infection with *Schistosoma haematobium* with resulting fibrosis is a common cause of bladder obstruction¹¹; although it is rare in industrialized nations, it should be suspected in patients from endemic areas such as Africa and the Middle East.

Intramural Causes

Congenital malformations of the genitourinary tract can cause intramural obstruction of the upper urinary tract. UPJ obstruction (UPJO) warrants specific mention, as it is the most common congenital genitourinary disorder likely to present in adulthood. Kinks, valves, or an adynamic segment of ureter results in failure of peristalsis at the UPJ.¹² The widespread use of maternal prenatal ultrasound (US) has led to increased antenatal diagnosis of UPJO. The diagnosis may be made by US, intravenous urography (IVU), or in equivocal cases, isotope renography (see later imaging section).

Another intramural cause of upper urinary tract obstruction is ureteral stricture due to genitourinary tuberculosis (GU TB). Although rare in the developed world, GU TB complicates up to 40% of patients with extrapulmonary tuberculosis.¹³ Hematogenous spread of mycobacteria can seed the renal cortex and ureters, causing inflammation with resultant fibrosis, obstruction, and secondary infections.¹³ Seeding of the retroperitoneum and bladder can also lead to complications in patients with GU TB.

More common are disorders affecting the neuromuscular control of the lower urinary tract such as cerebrovascular accidents,¹⁴ spinal cord injury,¹⁵ multiple sclerosis,¹⁶ and diabetic neuropathy,¹⁷ which may lead to bladder outlet obstruction. Multiple medications, including anticholinergics, opioid analgesics, nonsteroidal antiinflammatory agents, α -adrenoreceptor antagonists, benzodiazepines, and calcium channel blockers, have also been associated with urinary retention.¹⁸ Stricture of the urethra may also lead to obstruction.

Extrinsic Compression

Pregnancy is typically associated with right-sided dilation of the renal pelvis, calyx, and ureter. Hormonal mechanisms and mechanical compression from an enlarging uterus and ovarian vein plexus have been implicated in these changes.¹⁹ Clinically meaningful obstruction from the gravid uterus is extremely rare.

Malignancies can cause obstruction by several different mechanisms. Local ureteric compression may be seen in metastatic cancers of the cervix, bladder, and prostate, as well as with expanding retroperitoneal soft-tissue masses. Alternatively, the ureters may be compressed or encased by metastatic retroperitoneal lymphadenopathy.²⁰

Retroperitoneal fibrosis may lead to the obstruction of one or both ureters via inflammation. It is an uncommon disorder, with a reported incidence rate of 1.3 cases per million population and a male:female ratio of 3.3:1.²¹ Although the majority of these cases are idiopathic (>75%),²² numerous conditions are suspected to cause retroperitoneal fibrosis, including malignancies, medications, infection, trauma, radiation, and IgG4-related systemic disease.^{23,24} Treatment of idiopathic retroperitoneal fibrosis is initially with steroids, but recurrences are common. Case reports have described the use of cyclophosphamide, azathioprine, colchicine, mycophenolate, or tamoxifen for treatment relapses or steroid-resistant disease, although conclusive data are absent.²²

Abdominal aortic aneurysms (AAA) may also cause obstruction due to compression of the ureter or via inflammation. A recent series evaluated 999 cases of inflammatory AAA and found preoperative hydronephrosis in 7.4% of these cases.²⁵ The clinician must always bear in mind that hydroureter and/or hydronephrosis may be absent in obstruction due to retroperitoneal processes. Thus, one must maintain a high degree of suspicion and use alternative imaging modalities when considering these disorders.

One congenital extrinsic cause of obstruction at the UPJ includes abnormal rotation of the kidney during development, leading to ureteral compression and entrapment of the ureter by blood vessels, although significant controversy exists regarding this disease.^{12,26}

Extrinsic compression of the lower urinary tract is more common in males, and the cause is usually either benign prostatic hypertrophy or prostate cancer. The etiology of urinary tract obstruction is summarized in [Box 110-1](#).

CLINICAL PRESENTATION

The clinical presentation of urinary tract obstruction depends on the location, duration, and severity of obstruction and may therefore be quite variable.

Pain

Acute ureteral obstruction often presents with severe flank pain, otherwise known as *renal colic*. This is usually due to urolithiasis but may be due to other causes of ureteral obstruction (see earlier). Obstruction causes increased intraluminal pressure and spasm of the ureteral muscles, which are responsible for the colicky pain.²⁷ Partial ureteral obstruction may present with a chronic dull pain. Bladder outlet obstruction may lead to distention and subsequent abdominal discomfort.

Changes in Urine Output

One pitfall in the diagnosis of obstruction is the expectation that patients will be anuric. While this is true of patients with the obstruction of all functioning renal mass—complete bilateral ureteral obstruction, complete obstruction of a solitary functioning kidney, or complete obstruction distal to the bladder neck—this is not the case in patients with less severe disease. The degree of urine output does not reliably predict the presence or absence of obstruction; patients may present with normal urine output or even polyuria due to the effects of obstruction on renal salt and water handling (reviewed later).

Lower Urinary Tract Symptoms

Obstruction of the lower urinary tract often presents with some or all of a constellation of symptoms known collectively as *lower urinary tract symptoms*, or *LUTS*. LUTS include voiding symptoms (difficulty urinating, incomplete emptying), postmicturition symptoms (postvoid dribbling), and storage symptoms (urgency, frequency, hesitancy, incontinence).²⁸ Alternatively, patients with lower urinary tract obstruction may be asymptomatic.

BOX 110-1 Causes of Urinary Tract Obstruction

INTRINSIC CAUSES

Intraluminal

Renal Tubules

Crystal-induced disease
Uric acid nephropathy
Cast nephropathy (in multiple myeloma)

Upper Urinary Tract

Nephrolithiasis
Neoplasms
Blood clots
Sloughed renal papillae

Lower Urinary Tract

Urolithiasis
Blood clots
Neoplasms
Schistosomiasis

Intramural

Upper Urinary Tract

Congenital ureteropelvic junction obstruction
Genitourinary tuberculosis

Lower Urinary Tract

Disorders affecting neuromuscular control
Cerebrovascular accident
Spinal cord injury
Multiple sclerosis
Diabetic neuropathy
Medications
Anticholinergic agents
Opiates
Nonsteroidal antiinflammatory agents
 α -Adrenoreceptor antagonists
Benzodiazepines
Calcium channel blockers
Urethral structure

EXTRINSIC CAUSES

Upper Urinary Tract

Pregnancy
Malignancy
Retroperitoneal fibrosis
Abdominal aortic aneurysms

Lower Urinary Tract

Benign prostatic hypertrophy
Prostate cancer

Renal Dysfunction

If asymptomatic, the initial clue to the underlying obstruction may be elevated serum creatinine on blood drawn for an unrelated reason. The fact that urinary tract obstruction may be asymptomatic mandates its inclusion in the differential diagnosis of unexplained kidney failure. If blood work is not obtained during the course of the obstruction, the kidney function may deteriorate such that the first presentation is with uremic symptoms and the need for dialysis.

Infection

The urinary retention associated with lower urinary tract obstruction provides an excellent culture medium for bacteria. Patients may present with cystitis, pyelonephritis, or sepsis. An obstructing renal stone may also be a nidus for infection. Recurrent infection should raise suspicion for possible anatomic abnormalities, especially in men. In one study, 25 out of 83 men (30%) with a febrile urinary tract infection had anatomic lesions in the lower urinary tract, supporting imaging of the lower tract in men with this presentation.²⁹ More recent data refute this finding in men younger than 45 years old.³⁰

Laboratory Values

There are no laboratory values specific to obstruction. Blood tests may show no abnormalities or may show values consistent with kidney failure, such as elevated blood urea nitrogen, creatinine, potassium, and phosphorus levels, and decreased calcium, bicarbonate, and hemoglobin values. The blood tests may also be indicative of renal tubular acidosis (RTA; see later). The urinalysis may be bland or may include red blood cells (in the setting of a stone or malignancy) or white blood cells (in the setting of infection). Significant albuminuria is uncommon, although low-grade proteinuria can be observed, especially in the setting of infection. An experienced observer may also be able to discern crystals in freshly voided urine. The fractional excretion of sodium (FE_{Na}) may be less than 1% in acute obstruction, but it is generally greater than 1% when the obstruction is chronic, owing to renal tubular dysfunction.

IMAGING IN URINARY TRACT OBSTRUCTION

Various imaging modalities may be used to diagnose obstruction: plain abdominal radiography, US, computed tomography (CT), IVU, retrograde pyelography, and nuclear scanning. It is important to understand the indications and limitations of each modality.

Plain Abdominal Radiography

Abdominal radiography (kidney, ureter, and bladder [KUB]) is often the first imaging modality performed in patients with acute flank pain. Although most stones are composed of calcium and should in theory be visible, only 59% of stones are detected on plain film.³¹ Compared with CT scanning, the sensitivity and specificity of abdominal films were 45% to 59% and 77%, respectively.³¹ Further, plain films may not always be able to differentiate phleboliths from calculi. This limits the utility of plain abdominal films to the diagnosis of recurrent disease in those with known radiopaque stones.

Ultrasound

US is inexpensive, does not expose the patient to radiation, and is typically readily available. Its accuracy in detecting hydronephrosis makes US a good screening tool for obstruction in patients with unexplained kidney failure or patients with suspected lower urinary tract obstruction (Fig. 110-1). When CT is used as a reference, US has a traditionally reported sensitivity of 24% and a specificity of 90% for

FIGURE 110-1 ■ Typical appearance of a hydronephrotic kidney showing renal pelvis and calyceal dilatation. Note the increase in the kidney length (14.34 cm) compared with normal (~10-11 cm).

the detection of kidney stones and is likely to miss those less than 3 mm in size.³² Another disadvantage of US compared with CT is that bowel gas may obscure visualization of the ureters.³³ Other conditions such as peripelvic cysts and renal artery aneurysms may mimic hydronephrosis on US.³³ These conditions are easily distinguished via CT scanning.

However, in a recent large multicenter randomized controlled trial of adults presenting to the emergency department with suspected nephrolithiasis, US was found to be noninferior with regard to the rates of repeat hospitalizations for missed high-risk diagnoses and adverse events as compared with CT.³⁴ Additionally, US may be the initial imaging modality of choice when radiation is contraindicated, such as in pregnant women and children.

Computed Tomography

The major utility of CT scanning as it relates to urinary tract obstruction is in the evaluation of acute flank pain and suspected nephrolithiasis (Fig. 110-2). In this setting, CT offers a sensitivity of 96% and a specificity of 98% for the detection of stones.³⁵ The retroperitoneum is also well visualized, making CT ideal to detect retroperitoneal fibrosis or obstruction due to retroperitoneal lymphadenopathy. In addition to defining the anatomy of the collecting system, CT has the added benefit of visualizing other organ systems, thereby providing information regarding other conditions in the differential diagnosis of acute flank pain.

One concern raised with CT scanning is the high radiation dose administered. Each CT scan is equivalent to approximately 10 KUBs.³⁶ The reported dose of radiation, quantified in millisieverts (mSv), was significantly higher in patients initially undergoing CT (14.1 mSv) versus US (4.7 to 6.5 mSv) when presenting to the emergency department with acute flank pain and suspected nephrolithiasis.³⁴ Furthermore, this initial radiation exposure was cumulative and persisted at 6 months with CT (17.2 mSv) versus US (9.3-10.1 mSv) regardless of subsequent imaging.³⁴ Lower dose radiation CT protocols have previously been investigated. One study found that lower dose radiation CT scans (equivalent to that of plain film) have a sensitivity of 97% and a specificity of 96% for the diagnosis of acute renal colic when compared with the standard dose. The lower dose CT was inferior at detecting stones less than 3 mm in size,³⁷ which may impair its ability to diagnose non-collecting system pathology. Because of these limitations, it is unclear whether or not spiral CT will remain the initial imaging procedure of choice for the evaluation of suspected nephrolithiasis.

FIGURE 110-2 ■ Bilateral nephrolithiasis on an unenhanced computed tomography scan. Note the staghorn appearance on the left.

FIGURE 110-3 ■ Renogram showing left-sided obstruction. Note that both kidneys take up the tracer. On the right side, this is followed by an excretion of the tracer, whereas on the left, the tracer remains at peak value.

Isotope Renography

In conventional renography, radiographic tracers are injected into the patient's bloodstream and renal uptake and excretion are measured with a scintillation counter (Fig. 110-3). This test provides functional information by demonstrating decreased excretion in an obstructed kidney. The sensitivity of the test may be enhanced by administering a loop diuretic prior to the scan. The increased urine flow may unmask an occult obstruction. Isotope renography may be used if obstruction is suspected clinically but hydronephrosis is absent or to diagnose a nonobstructive cause of hydronephrosis. In this case, excretion will be normal despite the presence of hydronephrosis. However, as it is a functional scan, radiotracer uptake can be diminished and excretion prolonged with severely compromised GFR. This may lead to both false-negative and false-positive results, limiting its use in such situations.³⁸ Renography also does not provide anatomic information.

Intravenous Urography

IVU, in which the collecting system is imaged after the administration of intravenous (IV) contrast, used to be the study of choice for patients with acute flank pain. The need to administer nephrotoxic IV contrast and the delay in obtaining information render IVU less attractive than a CT scan.³⁵

Retrograde Pyelography

CT scanning and US have largely superseded retrograde pyelography for the diagnosis of obstruction. Retrograde pyelography may be indicated when obstruction is highly suspected on clinical grounds, the US is negative for hydronephrosis, and the patient is unable to receive IV contrast.¹

■ PATHOPHYSIOLOGY OF OBSTRUCTION

Urinary tract obstruction may cause intrinsic kidney dysfunction. The most important effects are changes in renal blood flow, increased

tubular hydrostatic pressure (as a result of increased ureteral pressure), and the development of fibrosis in long-standing obstruction. Specific tubular derangements in sodium, water, potassium, acid, and divalent cation handling occur as well.

Changes in Renal Blood Flow, Tubular Hydrostatic Pressure, and Glomerular Filtration Rate

Over the past 3 decades, various animal models have provided a basis for understanding the renal hemodynamic changes with urinary obstruction. The initial renal response to obstruction follows a triphasic pattern.³⁹ During the first 2 hours of obstruction, there is an initial increase in both renal blood flow and ureteral pressure. This is followed by a brief (2-3 hour) period in which renal blood flow declines due to increased afferent arteriolar resistance, yet ureteral pressures continue to rise. Ultimately, the decrease in renal blood flow leads to a decrease in ureteral pressure, with the pressure returning to normal levels by 10 to 12 hours after obstruction.

The glomerular filtration rate (GFR), which is determined by Starling's forces between the glomerular capillary and renal tubules, is initially diminished by transmitted tubular hydrostatic pressure but is maintained by the augmented renal blood flow. Unresolved obstruction leads to persistent afferent arteriolar constriction and a sustained decrease in both renal blood flow and GFR.

Structural Changes, Maladaptive Cell Signaling, and Renal Fibrosis

Early in ureteral obstruction, dilatation of the ureter and renal pelvis causes mechanical compression of the medulla and cortex, with tubular injury progressing in a retrograde manner.⁴⁰ Injured tubular epithelial cells lose polarity and likely de-differentiate, secreting chemokines that recruit circulating myeloid cells. A complex feed-forward loop of inflammatory cell signaling and oxidative stress ensues in the renal microenvironment.^{41,42} If obstruction is not reversed, cellular apoptosis, senescence, capillary rarefaction, and the formation of atubular

glomeruli are observed.⁴² These changes ultimately result in the deposition of fibrillar collagen, with the contraction and loss of renal parenchymal volume typical of an end-stage kidney.

As with other progressive renal diseases, angiotensin-2 (AT-2) plays a central role in the perpetuation of renal parenchymal damage in chronic obstructive nephropathy. Independent of its vasoconstrictive properties, AT-2 has many other biologic functions, including the upregulation of several profibrotic mediators such as transforming growth factor beta-1, tumor necrosis factor alpha, and nuclear factor kappa B.⁴³

Given the importance of the renin-angiotensin system in promoting renal injury after obstruction, antagonizing AT-2 would appear to be a viable strategy to attenuate injury. Although human data are lacking, animal data show benefits, provided the intervention is conducted after renal development is complete.⁴² Other therapies to halt or reverse fibrosis in urinary obstruction have shown proof of principle in animal models but have not yet translated to clinical use in humans.

Tubular Function

Tubular responses to unilateral or bilateral obstruction differ, with bilateral obstruction (or unilateral obstruction in a patient with a solitary kidney) being much more severe and having more important clinical implications. The following discussion will be limited to bilateral obstruction. Urinary tract obstruction impairs all aspects of renal tubular function including the ability to transport sodium, potassium, and hydrogen and to regulate urine concentration.

Sodium Reabsorption

Upon release of a bilateral obstruction, sodium excretion increases five to nine times that of normal.⁴⁴ Because the GFR is also decreased due to the obstruction, the FE_{Na} may be 20 times higher than normal.⁴⁴ Clinically, this failure of sodium reabsorption may manifest as hypovolemia.

Sodium reabsorption in the kidney is accomplished by various apical membrane transporters, which are coupled to the basolateral sodium-potassium ATPase. Many of these transporters, including the sodium/proton exchanger, sodium-phosphate cotransporter, sodium-potassium-2/chloride cotransporter, and thiazide-sensitive cotransporter, are downregulated during and after the release of the obstruction.⁴⁵ Recent studies suggest that the amiloride-sensitive epithelial sodium channel may be downregulated as well.⁴⁶ In addition to the downregulation of transporters, upregulation of atrial natriuretic peptide, a potent stimulus for sodium excretion, has been demonstrated during and after the release of bilateral obstruction.⁴⁷

Renal Water Handling

Several mechanisms render the kidneys unable to either concentrate or dilute urine after the release of an obstruction. In the case of urinary concentration, the sodium-potassium-2/chloride cotransporter is required to establish the medullary concentration gradient needed for osmotic water movement out of the collecting tubule. Dilution requires the removal of solute in both the loop of Henle and distal convoluted tubule via the sodium-potassium-2/chloride cotransporter and the thiazide-sensitive cotransporter, respectively. Osmotic diuresis due to retained solutes may also lead to an inability to conserve water.

In addition to the effects of abnormal sodium reabsorption on water metabolism in the postobstructed kidney, animal data have demonstrated a direct role of antidiuretic hormone in the concentrating defect as well. Many studies have shown a downregulation of aquaporins in the obstructed kidney,⁴⁸⁻⁵⁰ which may persist for weeks, accompanied by a long-term defect in urinary concentration.⁴⁸ Clinically, this inability to conserve water may manifest as nephrogenic diabetes insipidus and hypernatremia.

Acid-Base and Potassium Balance

Acid-base balance is accomplished by reclamation of filtered bicarbonate and excretion of acid, either as titratable acidity (buffering of hydrogen ions by phosphates, sulfates, and other buffers) or by ammonium excretion. Clinically, obstructed or postobstructed patients often manifest hyperkalemic, hyperchloremic metabolic acidosis. Although this may be solely due to the decreased GFR, some patients have persistent metabolic abnormalities long after the release of obstruction and stabilization of GFR.⁵¹ Human data have revealed several pathophysiologic mechanisms. The majority of patients studied have a distal RTA in which systemic acidosis did not lower the urinary pH below 5.5.⁵¹ Abnormalities in sodium transport in the distal nephron (see earlier) may render this tubular segment unable to generate the lumen negative transepithelial difference needed for proton excretion—a so-called voltage-dependent defect.⁵² This voltage defect can also lead to potassium retention and hyperkalemia.

Other patients are able to acidify their urine to a pH of below 5.5. These patients have low plasma levels of aldosterone with subsequent hyperkalemia, which is typical of a type 4 RTA.⁵¹ The underlying mechanism in this case is decreased ammoniogenesis, most likely due to the hyperkalemia, although the hypoaldosteronism may also contribute.⁵² Patients with a type 4 RTA retain the ability to excrete acid (via titratable acidity) and usually have a mild, self-limited acidosis, whereas those with a distal RTA cannot excrete acid, and the resultant acidosis may be severe.

Recent animal studies have also demonstrated downregulation of key renal acid-base transporters in urinary tract obstruction, including the cortical and medullary sodium hydrogen exchanger and several basolateral sodium-bicarbonate transporters.⁵³

Postobstructive Diuresis

The release of a bilateral obstruction (or unilateral obstruction of a solitary kidney) may lead to a profound diuresis. Several of the mechanisms have already been described. Defects in sodium and water handling predispose to large urinary losses of both. The osmotic load of retained solutes also contributes. Much of the diuresis is appropriate, however, in that previously retained salt and water must be excreted. Typically, postobstructive diuresis is mild and transient and requires no treatment. Often the degree and duration of this diuresis is worsened by overzealous fluid administration in the face of a large, but potentially appropriate, urine output.

The clinical manifestations of post-obstructive diuresis that require treatment include volume depletion and hypernatremia (which may be managed by the administration of iso-osmotic and hypo-osmotic fluid, respectively). Careful attention to potassium, magnesium, phosphorus, and calcium levels is warranted as well.

Other Tubular Functions

After the release of bilateral obstruction, phosphorus excretion rises proportionally to sodium excretion.⁴⁴ This may be mediated by a decrease in the number of proximal sodium/phosphate cotransporters.⁴⁵ Magnesium excretion also rises, likely from decreased absorption in the thick ascending loop of Henle due to a decrease in the transepithelial voltage difference created by the decreased sodium-potassium-2/chloride cotransporter activity.⁴⁴ Calcium handling after obstruction is unclear and differs depending upon the species studied.⁴⁴

TREATMENT

Management of obstructive uropathy depends on the location, severity, symptomatology, and etiology of the obstruction, as well as the presence of concomitant factors such as infection or a decline in kidney function. The clinical scenario guides timing and whether initial management should be conservative or aimed at reestablishing the patency of the urinary tract. Chronic asymptomatic partial obstruction does

not need emergent release, whereas acute, complete obstruction accompanied by infection, pain, or evidence of kidney dysfunction does.

Lower tract obstruction may be relieved simply by placing a urethral catheter, whereas upper urinary tract obstructions may be managed either with percutaneously inserted nephrostomy tubes or via retrograde (i.e., via cystoscope) ureteral stenting. In both cases, subsequent input from a urologist for specific therapy and follow-up is indicated.

Factors that may cause or exacerbate obstruction, such as constipation or the use of medications associated with urinary retention, should be addressed. Other supportive measures such as antibiotics and IV hydration should be instituted if clinically warranted. The metabolic abnormalities of kidney failure, particularly hyperkalemia, should be addressed. If needed, dialysis should not be withheld while awaiting decompressive therapy.

Should the obstruction be chronic and the kidney deemed non-functional, it may be appropriate to proceed with nephrectomy if there is persistent pain or unresolved infection. This decision requires an estimate of the likelihood of recovery of kidney function.

RECOVERY OF KIDNEY FUNCTION

Whether or not an obstructed kidney will regain function is of paramount importance to the clinician and may dictate whether aggressive interventions are indicated or if the affected kidney should be removed. Unfortunately, data addressing this question, particularly human data, are scant. Currently, there are no methods available that reliability predict kidney recovery after relief of an obstruction,⁴⁴ although one recent study found that a GFR of less than 10 mL/min in the obstructed kidney and abnormal renal perfusion (determined via isotope renography) predicted poor recovery in patients with unilateral ureteral occlusion.⁵⁵

Animal studies demonstrate that the likelihood of renal recovery diminishes with longer duration of obstruction.⁴⁴ Even with the recovery of GFR, there may be ongoing injury and progressive long-term kidney damage after the release of the obstruction, likely due to interstitial fibrosis associated with prolonged urinary tract obstruction.⁵⁵ In

humans, the cutoff point at which renal function is unlikely to return has not been determined, and partial recovery has been seen even after months of obstruction,⁵⁶ suggesting that all obstructions should be relieved and followed by serial determinations of kidney function. If desired, a kidney biopsy may be performed to assess the degree of interstitial fibrosis and provide prognostic information.

KEY POINTS

1. Urinary tract obstruction may be due to pathology anywhere from the renal tubules to the tip of the urethra and should be considered in all cases of unexplained kidney injury.
2. Upper urinary tract obstruction may present as renal colic with or without hematuria. Lower tract obstruction may present with frequency, urgency, nocturia, hesitancy, and incomplete emptying. Urinary tract obstruction may also be completely asymptomatic.
3. The presence of urine output does not exclude urinary tract obstruction.
4. Due to its sensitivity, CT is the most commonly used initial imaging modality for suspected nephrolithiasis; however, this practice has been challenged by recent data comparing US with CT.
5. Renal tubular dysfunction may manifest as sodium wasting, abnormal water handling, and acidosis with or without hyperkalemia.
6. Release of obstruction may result in postobstructive diuresis. The diuresis is usually an appropriate response to the retention of nitrogenous waste products.
7. Recovery of renal function is dependent on the duration of obstruction, with reports of recovery in patients who were dependent on dialysis for months.

ANNOTATED REFERENCES

Chevalier R, Thornhill B, Forbes M, Kiley S. Mechanisms of renal injury and progression of renal disease in congenital obstructive nephropathy. *Pediatr Nephrol* 2010;25:687-97.

This article reviews the cellular and molecular mechanisms responsible for the progressive kidney injury associated with obstruction. Pertinent cytokines and growth factors, as well as mediators of renal injury, are discussed. The authors discuss current and future strategies for preventing this injury.

Li C, Wang W, Kwon TH, et al. Altered expression of major renal Na transporters in rats with bilateral ureteral obstruction and release of obstruction. *Am J Physiol Renal Physiol* 2003;285:F889-901.

This article provides the molecular basis for the salt wasting observed after relief of bilateral obstruction. Levels of expression of renal sodium transporters were examined in rats after 24 hours of bilateral ureteral obstruction and at days 3 and 14 after relief of the obstruction. This article demonstrates the downregulation of essentially all transporters during obstruction and the rates at which transporter function begins to normalize.

Shokeir AA. Renal colic: new concepts related to pathophysiology, diagnosis and treatment. *Curr Opin Urol* 2002;12:263-9.

This is an excellent overall review to the approach of renal colic. Newer data regarding pathophysiology, diagnosis, and treatment are reviewed. The article provides a rational approach to imaging in this disorder, focusing on the newer imaging modalities.

Smith-Bindman R, Aubin C, Bailitz J, et al. Ultrasonography versus computed tomography for suspected nephrolithiasis. *N Engl J Med* 2014;371(12):1100-10.

This trial randomized patients presenting to the emergency department (ED) with suspected nephrolithiasis to initial ultrasound (US) performed by ED personnel or a US technician versus spiral computed tomography (CT). As compared with CT, both US arms were noninferior with respect to missed major diagnoses at 30 days, adverse events, and the rates of return ED visits and hospitalizations. Cumulative radiation exposure at 6 months was also lower in both US arms.

Vaughan JED, Marion D, Poppas DP, Felsen D. Pathophysiology of unilateral ureteral obstruction: studies from Charlottesville to New York. *J Urol* 2004;172:2563-9.

This study provides an excellent overview of the changes in renal tubular function during obstruction. The authors provide data implicating upregulation of the renal renin-angiotensin-aldosterone system. The mechanisms of fibrosis are discussed, and the authors present current and future strategies to prevent the development and progression of kidney disease due to obstructive uropathy.

Iodinated contrast agents, which are administered intravascularly for medical imaging, are widely used pharmaceutical agents, with greater than 80 million doses administered annually.¹ While vital for diagnostic and therapeutic purposes, they can result in the impairment of kidney function, resulting in a condition called *contrast-induced acute kidney injury* (CI-AKI) or previously *contrast-induced nephropathy*. In most cases, kidney dysfunction due to contrast exposure is mild and transient and is only detected by sensitive tests. Clinically significant kidney injury is much less common, especially among individuals with previously normal kidney function.

CI-AKI has been traditionally defined as an absolute increase of 0.5 mg/dL (44 μ mol/L) or a relative increase of 25% in serum creatinine, within 72 hours, in the absence of another explanatory etiology.² However, the slightly different and more recent AKI Network definitions (absolute increase in serum creatinine of 0.3 mg/dL [26.4 μ mol/L] or a relative increase of 50% within 48 hours) have gained popularity in recent years.^{2,3} These definitions, however, are mainly used for research purposes and are likely to evolve further with the advent of biomarkers such as neutrophil gelatinase-associated lipocalin. For clinical purposes, severe AKI requiring renal replacement therapy (RRT, i.e., dialysis) is much more important. However, even milder forms of AKI, as defined above, are significant, since they not only result in longer hospital stays but also because they are associated with increased long-term morbidity and mortality.^{4,5}

Awareness of the factors predisposing to contrast-associated nephrotoxicity has increased over time to the point that clinicians may now overestimate the risk associated with some specific medical conditions. However, the increasing use of radiographic contrast media, possibly combined with increasing age and comorbidities of the treated population, has contributed to the continuing importance of CI-AKI. In reality, given the mild and transient nature of the AKI in most cases, it is the association with subsequent clinical adverse events that drives the current interest in preventing CI-AKI.

EPIDEMIOLOGY

CI-AKI is the most common iatrogenic cause of AKI and overall the third most common cause of AKI in the hospital setting.^{6,7} The actual incidence of AKI after contrast-enhanced imaging varies from as low as 1% to as high as 30% and depends on the nature of the contrast administered and the underlying risk factors in the patient population.⁸⁻¹³ In addition, these estimates are clouded by the fact that AKI after contrast administration can often be caused by other etiologies (e.g., acute tubular necrosis from cardiogenic shock in a patient with acute coronary syndrome undergoing coronary angiography or severe sepsis in a patient undergoing a contrast-enhanced computed tomography [CT] scan, or atheroembolic renal disease^{14,15}), leading some researchers to use the term *contrast-associated AKI*.¹⁶

The risk of contrast nephropathy varies with the route of administration. Typically, after elective coronary angiography, about 10% to 15% of patients develop AKI (as defined by the rise in creatinine), although the incidence of severe AKI requiring dialysis is much lower, at less than 1%. The incidence of AKI after intravenous administration of contrast (as with contrast-enhanced CT scans) is believed to be much lower. A prospective study reported this incidence at 2.5%

overall, with the risk sequentially increasing as the underlying baseline kidney function decreases.¹⁷ However, other studies have questioned whether the true incidence of contrast nephropathy after intravenous contrast is this high, given that there are underlying fluctuations in serum creatinine levels.¹⁸ Recent studies that incorporated propensity-matched controls who did not receive contrast have made a reasonable case that there is little additional increase in AKI after intravenous contrast administration when adjusted for the underlying baseline risk of AKI.^{19,20} Given that there is possible selection bias in such observational studies (i.e., patients at high risk of AKI may not receive contrast and may be overrepresented in the controls), the debate whether intravenous contrast causes CI-AKI continues.

The most important underlying risk factor for development of CI-AKI is compromised baseline kidney function. The incidence is less than 2% in the unselected general population but has been reported to be as high as 20% to 30% with the addition of decreased kidney function and other risk factors.²¹ The incidence of CI-AKI increases in a graded manner as the severity of the underlying kidney function worsens. Among patients undergoing percutaneous coronary intervention, the risk of AKI has been reported²¹ to be just under 20%, with a baseline glomerular filtration rate (GFR) of less than 60 mL/min/1.73 m², compared with less than 1% in unselected populations.²² For outpatient CT scans, the risk has been reported to increase from 2.4% (GFR 45-59 mL/min/1.73 m²) to 11.1% (GFR 30-44 mL/min/1.73 m²) in one study²³ and to be at 0% (GFR 45-59 mL/min/1.73 m²), 2.9% (GFR 30-44 mL/min/1.73 m²), and 12.1% (GFR <30 mL/min/1.73 m²) in another study,¹⁷ with protocolized prophylactic measures playing a role, among other factors, for the lower risk in the latter case.

Other risk factors for CI-AKI described in the literature include diabetes, older age, cirrhosis, proteinuria, and other comorbid conditions, including congestive heart failure, hypotension, volume depletion, and concomitant administration of other nephrotoxic agents (e.g., nonsteroidal antiinflammatory drugs). It is unclear if some of these risk factors constitute an additional risk after adjusting for the underlying GFR. In addition, some of these risk factors, such as hypotension and congestive heart failure, are risk factors for AKI irrespective of contrast administration. A risk score that incorporates many of these factors for the development of AKI after percutaneous coronary interventions has also been described²⁴ and is available in online calculators and apps.

Metformin is often considered to be a risk factor for CI-AKI (since the package insert advises withholding it for at least 48 hours before contrast imaging), but this is untrue. In patients who develop AKI, there is a higher incidence of metformin-associated lactic acidosis, which is associated with a high fatality rate. However, metformin-associated lactic acidosis only occurs in a fraction of those patients who are not only taking metformin but also either have unstable kidney function at baseline or do develop severe CI-AKI and in whom the recognition of kidney failure does not result in discontinuation of the metformin.^{25,26}

Among patients who are already dialysis dependent, either on peritoneal dialysis (in which they often do have significant residual kidney function) or on hemodialysis, contrast imaging does not cause a decline in the residual kidney function.^{27,28} There is no role for early or intensive dialysis to remove contrast material in these patients.

■ PATHOPHYSIOLOGY

Decreased renal blood flow, tubular cell damage, and tubular obstruction are the most commonly described pathways to AKI occurring after contrast administration.²⁹ Coronary angiography and left ventriculography have been shown to cause a decrease in renal blood flow measured directly using renal artery catheterization.³⁰ In addition, animal data suggest differential vasoconstriction of afferent more than efferent arterioles, causing a direct effect on decreasing GFR.³¹ The vasoconstriction also occurs in the renal medulla, via decreased blood flow in the vasa recta.³² Tissue hypoxia then results in free radical release, leading to oxidant damage to the tubular cells from reactive oxygen species.³² Tubular filtration of relatively higher osmolar contrast media also results in osmotic diuresis, increasing medullary oxygen consumption and exacerbating the medullary hypoxia. Last, reabsorption of water leaves a high concentration of viscous contrast material in the tubules, which can result in intratubular physical obstruction.²⁹

■ CLINICAL FEATURES AND DIAGNOSIS

Patients with CI-AKI are generally asymptomatic but have an acute rise in serum creatinine concentration 24 to 72 hours after the administration of the contrast agent.³³ Kidney failure is usually nonoliguric in mild cases, but it may be oliguric, especially if there is significant preexisting renal impairment.³⁴ Clinically significant deterioration is unlikely if the serum creatinine concentration does not increase by more than 0.5 mg/dL within 24 hours.³³ To make an unequivocal diagnosis of CI-AKI, other potential causes of AKI must be ruled out. Prerenal factors, atheroembolic disease, and other nephrotoxic insults should be excluded.^{14,15} The relatively rapid onset and typical course may help differentiate CI-AKI from other causes of AKI. Urinalysis may be unremarkable or may show granular casts, tubular cells, or small amounts of proteinuria. Fractional excretion of sodium may be low and is unhelpful in differentiating CI-AKI from prerenal, volume-responsive causes of AKI.³⁴

■ PROGNOSIS

Usually, the natural course of CI-AKI is peak creatinine (i.e., the lowest point of kidney function) occurring between 24 and 72 hours and then relatively rapid improvement over the next few days to baseline serum creatinine levels by 7 to 14 days.³³ Overall, less than 1% of patients with CI-AKI will develop kidney failure that requires dialysis, and a smaller proportion of these (estimated at 10%-50%) will remain dialysis dependent. The minority that remains dialysis dependent consists of a mixture of cases of true CI-AKI along with atheroembolic disease and other causes of AKI that often occur in these patients.^{14,15} Nevertheless, despite the fact that most patients with CI-AKI recover, a large body of literature has emerged showing that an episode of AKI is associated with poor long-term outcomes, with a faster decline in kidney function and higher rates of subsequent RRT requirement, as well as higher rates of hospitalization for heart failure and all-cause mortality.^{4,35}

Although the association of CI-AKI with adverse clinical outcomes has been clearly and consistently shown, it is not yet known whether CI-AKI is on the causal pathway to these outcomes or if it is merely a marker of patients who are at high risk of these events.³⁶⁻³⁸ If the latter is true, CI-AKI may indeed be a less important health issue. Future trials using a variety of interventions with different mechanisms of action showing parallel diminution in CI-AKI and adverse events are required to establish more robust evidence for causality.

■ PREVENTION

The most effective method of preventing CI-AKI is to not give iodinated contrast unless absolutely essential, especially in patients at high risk, such as those with advanced kidney disease. Unfortunately, the risks with contrast-enhanced magnetic resonance imaging in this

patient population (i.e., the risk of nephrogenic systemic fibrosis from gadolinium),³⁹ also limit the imaging options, though these risks are much lower with the currently used cyclic gadolinium compounds.⁴⁰ Given the elective nature of the nephrotoxic insult that allows for attempting prophylaxis, many different interventions have been tested for CI-AKI prevention. Many of the studies are contradictory, and the numbers of systematic reviews and meta-analyses are also quite high, so the reader needs to look at the entire body of literature in order to interpret the data.⁴¹

Fluid Administration

Periprocedural volume administration has been the mainstay of preventive efforts and presumably works by reducing the concentration of the contrast medium in the tubules, improving medullary blood flow (via suppression of vasopressin), and increasing the urinary flow itself.²⁹ Isotonic saline has been shown to be superior to half-normal (0.45%) saline.²² There has been significant research in the possible superiority of a bicarbonate-based strategy compared with normal saline, under the hypothesis that the resultant alkaline urine in the tubules will decrease free radical formation and the subsequent oxidant tubular damage. However, the initial promise from the first trial has been belied by the results of subsequent larger trials and meta-analyses.⁴²⁻⁴⁵ A large ongoing prospective trial, which plans to enroll almost 9000 patients, may resolve this question.⁴⁶ Another approach with very promising results relied on using left ventricular end-diastolic pressure (LVEDP) to guide fluid administration in patients undergoing cardiac catheterization, with a relative risk of 0.41 (95% confidence interval: 0.22-0.79; $P = 0.005$) for CI-AKI compared with the standard saline protocol.⁴⁷ This trial also showed a reduction in clinically meaningful outcomes (reduction in persistent renal impairment and all-cause mortality at 6 months), although the number of events was small. Another point to be noted is that the intervention group received significantly larger amounts of fluid (mean 1727 mL compared with 812 mL in the control group), thus questioning the role of LVEDP-guided therapy vis-à-vis more fluid alone. Further, LVEDP measurement is not practical in many settings, such as intravenous contrast administration with CT scans, especially in outpatient settings. Small trials have tested oral hydration strategies compared with intravenous strategies, and although they may be as effective, the small numbers of events in these trials preclude any definitive recommendations at this stage.⁴⁸

Choice and Volume of Contrast Agent

Since the direct kidney damage occurs due to the contrast agent, significant research has been performed with respect to the physicochemical properties, specifically, the ionicity, osmolality, and viscosity, of the contrast agents and modifications to decrease CI-AKI (see [Table 111-1](#) for the classification of the different types). High-osmolality contrast agents, such as diatrizoate, have been shown to be worse with respect to low-osmolality agents and are thus no longer used in routine clinical practice.⁴⁹ When low-osmolality contrast agents were compared with iso-osmolar contrast agents (mainly iodixanol), the first trial showed a significantly lower risk of CI-AKI with iodixanol compared with iohexol¹⁵⁰; however, subsequent larger trials have had different results.^{13,51} Systematic reviews and meta-analyses have suggested the possibility of a small nonsignificant benefit with iodixanol but with significant heterogeneity. This heterogeneity has been resolved either by grouping trials based on the route of contrast (e.g., there is a lower risk of CI-AKI in intraarterial contrast imaging with iodixanol use⁵²) or by specific contrast agents (e.g., iodixanol resulted in less CI-AKI compared with iohexol but not with other low-osmolar agents⁵³). The volume of contrast agent administration also matters, suggesting a lower risk of CI-AKI with lower doses of contrast agent. A ratio of the volume (of contrast dose in mL) to creatinine clearance (variously from >2.6 to >4) has also been reported to be associated with a higher risk

TABLE 111-1 Classification of Iodinated Contrast Media

| IONICITY | RELATIVE OSMOLALITY | OSMOLALITY (MOSM/KG H ₂ O) | EXAMPLES |
|-------------------|---------------------|---------------------------------------|---|
| Ionic monomers | High osmolality | 1500-1900 | Diatrizoate, iothalamate, metrizoate, iodamide, ioxithalamate |
| Ionic dimers | Low osmolality | 600 | Ioxaglate |
| Nonionic monomers | Low osmolality | 500-700 | Iopamidol, iohexol, iomeprol, iopentol, iopromide, ioversol, ioxitol, metrizamide |
| Nonionic dimers | Iso-osmolal | 290-320 | Iodixanol, iotrolan |

of CI-AKI, suggesting that the higher the creatinine clearance, the lower the necessary volume of contrast agent.^{54,55}

Prophylactic RRT

Hemodialysis and hemofiltration, which are performed soon after contrast administration, have been studied for CI-AKI prevention with mixed results.⁵⁶ The rationale for doing this is to help remove the offending iodinated contrast material, especially in patients with reduced kidney function who may not be able to clear it quickly. However, biologically, the iodinated contrast material injected into, say, the coronary circulation or the left ventricle for ventriculography reaches and causes damage to the nephrons within a few cardiac cycles, so the efficacy of removing the contrast agent after the length of time it takes to set up RRT is not very plausible. Indeed, the results of the largest trial studying this were emphatically negative.^{57,58} Other trials have reported a decrease in the proportion of patients with a decrease in creatinine clearance on the fourth day post contrast administration⁵⁹ or even in in-hospital mortality.⁶⁰ These trials are very challenging to interpret given that the hemofiltration or hemodialysis itself would change creatinine clearance directly, and it is not possible to tease the effect of RRT on creatinine clearance from the effect of the CI-AKI attenuation. In addition, these procedures have inherent risks, such as those associated with central line placement and hemodynamic issues with the RRT procedure itself.⁵⁶

Pharmacologic Strategies

N-Acetylcysteine

N-acetylcysteine (NAC) replenishes endogenous glutathione, acts as a biological antioxidant, and may also possess antiinflammatory effects. It has been reported to reduce the risk of CI-AKI in a small trial⁶¹; however, subsequent trials have provided conflicting results. Heterogeneity with respect to the dose and route of administration, and the possible effect of NAC on creatinine levels rather than kidney function, make it difficult to determine the true efficacy of NAC.^{62,63} The largest trial on this topic, which included 2308 patients and measured not just CI-AKI on the basis of the change in creatinine but also clinical events such as the need for RRT and mortality, did not show any benefit of NAC.⁶⁴ Arguments regarding the benign nature of NAC should take into account that the intravenous route can cause anaphylactoid reactions.⁶⁵ In addition, although NAC is not expensive, oftentimes, it has been used in place of—rather than in addition to—truly effective prophylactic strategies such as volume expansion.⁶⁶ Thus, at present, NAC has no role in CI-AKI prevention strategies.

Diuretics

Diuretics, by their inherent effect, can increase urine flow and have been investigated for CI-AKI prevention since they may have a diluting effect on the iodinated contrast agent being filtered in the tubules. By themselves, the use of furosemide and mannitol has actually been shown to be detrimental⁶⁷ and increases the incidence of CI-AKI, which is not entirely unsurprising given the protective effect of volume expansion. More recently, however, the use of furosemide in addition

to intravenous fluids (in the “RenalGuard” system), dosed to achieve a urine output of >300 mL/h, at which point contrast administration is permitted, with subsequent titration of intravenous fluids (and furosemide as required) to match urine output, has been shown to be more effective than hydration alone.^{68,69} Of note, both the RenalGuard system and the LVEDP-guided hydration strategies result in a higher volume administered to the intervention group than to the controls, and the nature of both designs allows this to be performed in a safe manner.

Statins

Statins have been found to be protective as compared with placebo, as well as when high-dose statins (e.g., atorvastatin 80 mg) are compared with low-dose statins in the prevention of CI-AKI.^{70,71} However, these trials have been conducted in patients undergoing coronary angiography and/or interventions and not patients receiving intravenous contrast and typically enrolled limited numbers of patients with chronic kidney disease; therefore, these results cannot be easily translated into such populations. Last, under most current guidelines, the typical patient profile undergoing coronary angiography should be on a statin in the long term and not just for CI-AKI prevention.⁷²

Others

Small trials with ascorbic acid, calcium channel blockers, dopamine, fenoldopam, atrial natriuretic peptides, prostaglandin E1, and nonselective endothelin antagonists have all either failed to show any benefit in CI-AKI prevention or have shown benefit in small trials that need replication.⁷³⁻⁷⁷

MANAGEMENT

In most instances, CI-AKI never becomes clinically evident, and kidney function returns to baseline within 2 weeks. In more severe cases, management is no different from that for AKI of any other cause. Careful control of fluid and electrolyte balance, avoidance of further nephrotoxic insults, attention to nutrition, and surveillance for complications are generally all that is required, although dialysis may be necessary in the occasional patient. Indications for dialysis are no different from those in other patients with AKI, taking into account clinical and biochemical factors such as hyperkalemia and volume overload. Prophylactic hemodialysis soon after the administration of a contrast agent in patients with high serum creatinine concentrations has had inconsistent effects as previously noted. Moreover, dialysis should not be performed for routine removal of contrast medium after imaging in previously dialysis-dependent patients.

CONCLUSION

CI-AKI remains a concern, especially with interventions involving intraarterial contrast. CI-AKI is not common in the absence of risk factors, and these are generally detectable with a history and physical examination and the determination of the serum creatinine concentration. Since CI-AKI can be associated with other adverse clinical outcomes, preventive measures are advisable, especially with advanced

preexisting kidney disease when there is a risk that the patient may require dialysis. Although CI-AKI is associated with later adverse events, causality has not been proven, and the efficacy of preventive measures directed at CI-AKI in preventing these associated events has not been established. At this time, the optimal approach to prevent CI-AKI, which is summarized in the Key Points, includes minimizing the contrast dose, using either iodixanol or a low-osmolar contrast agent other than iohexol, and the use of isotonic sodium bicarbonate or saline. Ongoing trials will elucidate the validity of these approaches

and may especially refute or confirm the newer hydration strategies. Finally, supportive care is indicated if severe CI-AKI does occur.

■ ACKNOWLEDGMENTS

We would like to acknowledge M. Khaled Shamseddin and Brendan Barrett, the authors of the same chapter in the previous edition of this textbook. The present version is a revised version of their excellent overview of this topic.

KEY POINTS

Recommendations to Reduce the Risk of Contrast-Induced Acute Kidney Injury

1. Assess the risk of CI-AKI in patients requiring a contrast imaging test.
 - a. Use the Mehran risk score if the patient is undergoing percutaneous coronary intervention.
 - b. For patients undergoing intravenous contrast administration, consider an estimated glomerular filtration rate <30 mL/min/1.73 m² as the principal risk factor.
 - c. Additional risk factors include:
 - i. Older age
 - ii. Diabetes mellitus
 - iii. Unstable kidney function
2. Assess the risk/benefit of the proposed contrast imaging, and consider alternative imaging in high-risk patients.
3. Modify correctable risk factors, and hold medications that may act as nephrotoxins.
4. Use the lowest possible dose of contrast media; consider using iodixanol or a low-osmolar contrast agent (other than iohexol)
5. In high-risk patients, correct dehydration, hold diuretics, and consider intravenous fluids if there are no contraindications. Either normal (0.9%) saline or isotonic sodium bicarbonate, started at an initial rate of 3 mL/kg/h at least 1 hour before and continued at 1 mL/kg/h for 6 hours later, are commonly recommended.
6. In high-risk patients, monitor creatinine within 24 to 72 hours post contrast administration.

Over half of all critically ill patients develop some degree of acute kidney injury (AKI), and nearly 5% require renal replacement therapy (RRT). For those with severe AKI requiring RRT, mortality can be as high as 70%, and up to 30% of surviving patients remain dialysis dependent.¹⁻⁶ AKI may be a consequence of prerenal causes, intrinsic kidney disease, or urinary tract obstruction. In critically ill patients, the majority of AKI is related to ischemic or toxic tubular injury that is treated supportively and is often reversible. AKI related to acute glomerulonephritis (GN) and acute interstitial nephritis (AIN) occurs in a smaller percentage of patients, but the incidence may be as high as 20% of all AKI.⁷ In addition to supportive care, initiation of appropriate management is paramount for optimal patient and renal survival. This chapter focuses on the clinical presentation and management of GN.

■ GLOMERULONEPHRITIS

Patients with GN most commonly present with features of the nephritic syndrome characterized by hematuria, proteinuria, AKI, edema, and hypertension.⁸ Hematuria may be microscopic or macroscopic, and the urine sediment demonstrates dysmorphic erythrocytes and erythrocyte casts. The urinary protein excretion typically exceeds 1 gram per day. Measuring the urine protein-to-creatinine and/or the urine albumin-to-creatinine ratio can rapidly assess the degree of proteinuria. The simultaneous measurement of these parameters enables one to calculate the urinary albumin-to-total protein ratio (UAPR; $\text{UAPR} = \text{urine albumin-to-creatinine ratio} \div \text{urine protein-to-creatinine ratio}$). A value less than 0.4 for the UAPR is most consistent with tubular or light chain proteinuria, whereas values greater than 0.6 suggest glomerular proteinuria.⁹ In some instances, patients may have nephrotic-range proteinuria (>3 g/d) with associated clinical manifestations including edema, hypoalbuminemia, and hyperlipidemia. Leukocyturia with or without white blood cell casts may be observed with GN of inflammatory origin but is more characteristic of interstitial nephritis.

In a biopsy series of patients with unexplained AKI, the most common diagnoses included various forms of GN (anti-neutrophil cytoplasmic antibody [ANCA]-associated GN, immunoglobulin [Ig] A nephropathy, postinfectious GN, lupus nephritis, anti-glomerular-basement-membrane [anti-GBM] disease) and AIN.^{7,10-12} Indeed, the third most common cause of end-stage renal disease (ESRD) in the United States and Europe is GN.⁸ Distinguishing the type of GN using kidney biopsy is critical for diagnosis and assessing the degree of acute versus chronic disease, which helps guide treatment and prognosis.

The most aggressive form of GN is described clinically as *rapidly progressive glomerulonephritis* (RPGN). Rather than a single disease entity, RPGN is the most severe form of many of the glomerular diseases that are divided into renal-limited etiologies and systemic diseases that involve the kidneys (Table 112-1). RPGN is defined as rapidly declining renal function, progressive oliguria, hematuria, proteinuria, and hypertension.⁸ Although many critically ill patients may have hematuria associated with infection or trauma, hematuria and AKI should always prompt consideration of acute GN. The kidney ultrasound in most cases of RPGN shows normal to slightly enlarged kidneys with increased echogenicity. Kidney biopsy reveals a high degree of glomerular injury with extensive crescent formation

(Fig. 112-1). Importantly, the transition from an acute cellular crescent to chronic, irreversible injury may occur rapidly over days. RPGN is a nephrologic emergency that requires prompt diagnosis with early intervention and therapy to interrupt a natural progression to chronic kidney disease. In adults, the most common cause of RPGN is ANCA-associated small-vessel vasculitis and GN, followed by immune-complex diseases such as lupus nephritis or mixed cryoglobulinemia, and anti-GBM disease (called Goodpasture disease when there is pulmonary involvement).^{8,13} Immunofluorescence microscopy shows pauci-immune staining in ANCA-associated GN, linear IgG staining of the GBM in anti-GBM disease, and immune complex deposition in lupus nephritis, IgA nephropathy, and infection-related GN.

Pulmonary renal syndrome characterized by RPGN and pulmonary capillaritis that may manifest as diffuse alveolar hemorrhage (DAH) is a medical emergency requiring early aggressive treatment.¹⁴⁻¹⁶ It is associated with high mortality rates and rapid progression to ESRD if left untreated. Admission to the intensive care unit (ICU) and mortality are related to both the disease itself and infection. Patients often present with dyspnea, fever, cough, and hemoptysis, with chest radiography documenting diffuse alveolar infiltrates. Alveolar hemorrhage may be difficult to distinguish from pneumonia, especially in patients without hemoptysis. Roughly 30% of patients with DAH do not have hemoptysis. The presence of AKI and hematuria in patients with pulmonary symptoms should raise suspicion of a pulmonary renal syndrome. Although the term *Goodpasture's syndrome* was first used in 1958 to describe patients presenting with pulmonary hemorrhage and GN,¹⁷ the most common cause of pulmonary renal syndrome is ANCA-associated small-vessel vasculitis.⁸ Anti-GBM disease now refers to the triad of DAH, RPGN, and the presence of anti-GBM antibodies. Goodpasture disease is the second most common cause of pulmonary renal syndrome. Much less common causes of pulmonary renal syndromes are SLE (systemic lupus erythematosus), thrombotic microangiopathies, and other systemic vasculitides.

A thorough history and physical examination may provide evidence for a systemic vasculitis (e.g., scleritis, purpuric rash, and oral or sinus lesions). Bronchoscopy is critical to confirm DAH and to evaluate for infection. The gold standard for diagnosis is kidney or lung biopsy, but critically ill patients are often high risk for these procedures. Kidney biopsy is favored over lung biopsy because it is relatively less invasive. Because ANCA-associated small-vessel vasculitis and anti-GBM disease are treated similarly in the acute setting of RPGN and DAH, treatment with plasma exchange, corticosteroids, and cyclophosphamide may be initiated rapidly, before knowing the results of serologic testing.

■ ANCA-ASSOCIATED SMALL-VESSEL VASCULITIS

ANCA-associated disease may present as a systemic small-vessel vasculitis, pulmonary renal syndrome, or renal limited disease. The spectrum of disease includes microscopic polyangiitis, granulomatosis with polyangiitis (GPA, formerly called Wegener granulomatosis), and eosinophilic granulomatosis with polyangiitis (EGPA, formerly called Churg-Strauss syndrome^{18,19}). Histopathology shows focal and segmental crescentic GN, fibrinoid necrosis, and a paucity of immune staining within the glomeruli by immunofluorescence microscopy.

TABLE 112-1

Diseases Associated with Rapidly Progressive Glomerulonephritis and Pertinent Laboratory Studies**RENAL LIMITED**

| | |
|--|--|
| IgA nephropathy | |
| Infection-related glomerulonephritis | Low complement, streptococcal serologies, bacterial cultures |
| ANCA-associated glomerulonephritis (pauci-immune glomerulonephritis) | ANCA titers |
| Anti-GBM disease (Goodpasture's syndrome) | Anti-GBM antibodies |

SYSTEMIC DISORDERS

| | |
|---|---|
| Lupus nephritis | Low complement, ANA, dsDNA antibodies |
| ANCA-associated small-vessel vasculitis | ANCA titers |
| Anti-GBM disease | Anti-GBM antibodies |
| Henoch-Schönlein purpura | None |
| Cryoglobulinemic vasculitis | Low complement, cryoglobulins, hepatitis C serologies, positive rheumatoid factor |

ANCA, antineutrophil cytoplasmic antibodies; ANA, antinuclear antibodies; dsDNA, double-stranded DNA; GBM, glomerular basement membrane; IgA, immunoglobulin A.

FIGURE 112-1 ■ Rapidly progressive glomerulonephritis. Cellular crescent is present in glomerulus (4- to 8-o'clock position), with fibrinoid necrosis of the glomerular capillary tuft (x200, trichrome).

Either anti-myeloperoxidase (MPO) or anti-proteinase 3 (PR3) antibodies are detectable in most patients. However, about 10% of patients with characteristic clinical manifestations of these diseases and pauci-immune GN do not have detectable antibodies.

Mortality of untreated disease is roughly 90% at 2 years following disease onset.²⁰ However, systematic studies of different treatment regimens have led to significant progress in this field and have improved patient outcomes.²¹ Approximately 80% to 85% of patients attain clinical remission with effective immunosuppressive strategies. Treatment consists of pulse intravenous (IV) methylprednisolone followed by oral corticosteroids and IV cyclophosphamide, rituximab, or both.^{15,22-27} Even patients who are dialysis dependent on presentation often recover renal function with appropriate treatment. Poor prognostic indicators for patient and renal survival are the presence of DAH, severity of renal injury at diagnosis, degree of glomerular injury, extent of

tubulointerstitial lesions on biopsy, and older age.²⁸⁻³² Patients with DAH have a high mortality rate, and plasma exchange improves patient survival. Coagulation factors should be replaced in patients with active hemorrhage.^{20,33-36} For severe pulmonary disease, a few patients have been successfully treated with ECMO (extracorporeal membrane oxygenation).^{37,38} Patients with severe renal disease (i.e., serum creatinine >5.7 mg/dL) have an increased likelihood of renal recovery when treated with plasma exchange. The ongoing “plasma exchange and glucocorticoid dosing in the treatment of anti-neutrophil cytoplasm antibody associated vasculitis (PEXIVAS) study” will clarify whether plasma exchange is of value in patients with a glomerular filtration rate less than 50 mL/min.^{29,31,35,39-41}

With appropriate treatment, roughly 80% to 90% of patients achieve remission.^{20,28,33,42,43} Treatment resistance is more common in women, blacks, and patients with severe renal disease. Relapse is more common in patients with anti-PR3 antibodies and involvement of the pulmonary and upper respiratory systems. The ANCA-associated small-vessel vasculitides (AAV) follow a remitting and relapsing course, with the exception of drug-induced AAV (e.g., levamisole-adulterated cocaine, hydralazine),⁴⁴ making long-term monitoring a key component of patient and kidney survival.

ANTI-GLOMERULAR-BASEMENT-MEMBRANE GLOMERULONEPHRITIS

Anti-GBM disease (Goodpasture disease when accompanied by pulmonary capillaritis) is characterized by DAH and RPGN with evidence of anti-GBM antibodies on serologic testing that target the noncollagenous domain of the $\alpha 3$ chain of type IV collagen. It is the most aggressive form of RPGN,¹³ and roughly 30% to 40% of patients have renal limited disease without pulmonary involvement. Anti-GBM disease is more common in white patients, with a bimodal age distribution that peaks during the third and seventh decades.^{15,45-47} Kidney biopsy shows fibrinoid necrosis and glomerular crescent formation, with linear deposition of IgG along the GBM.

Untreated anti-GBM disease is highly fatal. Death is usually caused by pulmonary hemorrhage or renal failure. Treatment with therapeutic plasma exchange, cytotoxic agents, and corticosteroids was introduced in the 1970s, resulting in improved patient and renal survival.⁴⁸ In patients with pulmonary and renal involvement, prompt initiation of plasma exchange is crucial for rapid clearance of anti-GBM antibodies⁴⁹ and should be continued daily until antibodies are undetectable.⁴⁷ Long-term outcomes are related to the degree of pulmonary compromise and renal dysfunction at presentation. With appropriate treatment, survival rates may exceed 90% for acute disease, but patients requiring RRT on initial presentation have lower survival rates.^{46,47,50} Fewer than 10% of patients with renal-limited anti-GBM disease requiring RRT at presentation recover renal function at 1 year despite treatment with plasma exchange, corticosteroids, and cyclophosphamide.^{46,50}

In contrast, one study demonstrated that patients with serum creatinine (SCr) below 5.7 mg/dL on presentation had 100% 1-year patient survival and 95% renal survival.⁵⁰ In addition to dialysis dependence and elevated creatinine, predictors of poor renal outcome include oligoanuria, high anti-GBM antibody titers, and a high percentage of glomeruli with crescent formation and extensive tubulointerstitial disease on renal biopsy.^{45,49,51,52} Although patient and renal survival is generally worse with anti-GBM disease than with ANCA-associated disease, late recurrence of anti-GBM disease is less common than recurrence of ANCA-associated disease.^{13,47}

Both ANCA-associated vasculitis and anti-GBM disease are rare, and interestingly, a subset of these patients has both types of antibodies on serologic testing. Roughly 15% to 30% of patients with ANCA-associated disease also have anti-GBM antibodies, while only 5% to 10% of patients with anti-GBM antibodies also have detectable ANCA titers.^{13,46,47,53-55} Although outcome data are limited in this small group of patients, the outcomes of these patients may be better than those with only anti-GBM antibodies.

LUPUS NEPHRITIS

Lupus nephritis occurs in 50% to 60% of patients with SLE during the first 10 years of disease and is present in 35% of patients at the time of initial diagnosis.⁵⁶ Less than 5% of patients have RPGN or pulmonary renal syndrome. However, 10% to 20% of patients with lupus nephritis ultimately progress to ESRD. In addition to history and physical examination, patient evaluation should include analysis of the urinary sediment because lupus nephritis may present as nephritic or nephrotic syndrome despite normal serum chemistries. Additional testing should also include quantification of proteinuria (by 24-hour urine when possible), measurement of serum complement levels, and assays for antinuclear antibodies (ANA) and anti-double-stranded DNA (anti-dsDNA) antibodies. Kidney biopsy is critical for diagnosis, prognosis, and guiding treatment.

Kidney biopsy is used to divide lupus nephritis into six categories according to the International Society of Nephrology (ISN) classification: class I, minimal mesangial lupus GN; class II, mesangial proliferative lupus GN; class III, focal proliferative lupus GN; class IV, diffuse proliferative lupus GN; class V, membranous lupus GN; and class VI, advanced sclerosing lupus GN.⁵⁷⁻⁵⁹ Proliferative lesions in class III/IV lupus nephritis have poor renal survival in the absence of aggressive treatment. These classes often present with hematuria, proteinuria, hypertension, and AKI. Sclerosing lupus nephritis is a chronic, irreversible lesion that carries a poor prognosis.

Treatment of the more severe forms of lupus nephritis includes pulse methylprednisolone followed by oral corticosteroids and IV cyclophosphamide.⁶⁰⁻⁶³ Similar to treatment of pauci-immune GN, pulse IV cyclophosphamide is preferred over oral cyclophosphamide. Over 80% of patients respond to treatment.^{60,64} Importantly, about 5% to 10% of patients who require RRT initially recover enough renal function to become dialysis independent following treatment.⁶⁵ Plasma exchange did not show additional benefit in a clinical trial using standard glucocorticoid plus cyclophosphamide for proliferative LN induction.⁶⁶ However, plasma exchange may have a role in select patients with LN and a microangiopathy caused by anti-phospholipid antibodies or ADAMTS13 antibodies.⁶⁷ Studies comparing mycophenolate mofetil (MMF) to cyclophosphamide show equivalence but not superiority of one agent over the other; however, relapse appears to be more common in patients treated with MMF.⁶⁸⁻⁷¹ Induction should be followed by maintenance therapy. MMF in combination with low-dose prednisone is the preferred regimen. Additional IV cyclophosphamide or oral azathioprine may be considered depending on response and side effects.^{60,72-74} Other potential therapies include abatacept and belimumab, but their incorporation into the treatment of lupus nephritis requires further study and validation.

Poor prognostic indicators at the onset of disease include male sex, black race, severe hypertension, antiphospholipid syndrome (APS), and delayed initiation of immunosuppressive therapy. Following induction treatment, poor prognostic indicators are failure to achieve remission at 6 months and uncontrolled hypertension.^{60,75} Roughly one-third to one-half of patients will have disease relapse. In some patients, falling complement levels and rising anti-dsDNA titers precede recurrence of disease. However, some patients with severe lupus nephritis have negative titers.^{60,76} Patients with only partial remission often recur sooner than those with complete remission and are more likely to progress to ESRD.⁷⁷ All patients with a history of lupus nephritis should be carefully monitored for recurrence of disease, and repeat kidney biopsy is often required to guide treatment decisions.

INFECTION-RELATED GLOMERULONEPHRITIS

Bacterial, viral, fungal, protozoal and helminth infections all can result in infection-associated glomerulonephritis. Poststreptococcal glomerulonephritis (PSGN) presents with nephritic syndrome 1 to 6 weeks after bacterial infection. It commonly occurs in children following a skin or pharyngeal infection with a nephritogenic strain of group A

β -hemolytic *Streptococcus*.^{78,79} Although PSGN remains the most common cause of acute nephritic syndrome in the pediatric population in developing countries, the incidence of this disease has declined dramatically in the industrialized world. Recently, cases of infection-related GN (IRGN) due to *Staphylococcus* and gram-negative bacteria have become more prevalent, especially in the setting of bacterial endocarditis and ventriculovascular shunt infections. In contrast to cases associated with group A β -hemolytic streptococci, renal insufficiency associated with *Staphylococcus* and other infections occurs during active infection.

Children with PSGN usually have nephritis characterized by hematuria, proteinuria, hypertension, edema, and mild renal impairment. Severe hypertension with encephalopathy and seizures is uncommon and may require admission to the ICU.^{80,81} Laboratory findings demonstrate depressed complement levels (CH50 and C3) consistent with activation of the alternate complement cascade; levels return to normal by 8 to 10 weeks.¹⁸ Serologic studies may be used to confirm recent streptococcal infection, particularly with recent pharyngitis.^{82,83} Renal biopsy demonstrates endocapillary proliferation and granular deposition of immune complexes by immunofluorescence microscopy.^{78,82,84,85}

The acute nephritic syndrome usually resolves in 7 to 14 days, and the prognosis of children with PSGN is excellent. However, about 10% to 20% of children have persistent urinary abnormalities including proteinuria and hematuria.^{6,8,83,86-88} Treatment is generally supportive, with antihypertensives and diuretics as needed in the acute phase. Active infections should be treated, and prophylactic antibiotics are often indicated in endemic areas and for household contacts in regions with high prevalence of disease.

In contrast to children, outcomes for IRGN in adults in the industrialized world are much worse, particularly for patients with underlying chronic disease or risk factors including diabetes, cancer, alcoholism, liver disease, or IV drug use.^{18,78,79,89-92} Elderly patients often have concurrent AKI, congestive heart failure, and nephrotic-range proteinuria. Treatment consists of supportive care including diuretics, antihypertensives, renal replacement therapy as indicated, and eradication of infection. Although evidence from randomized controlled trials is lacking, pulse IV methylprednisolone can be considered in patients with extensive glomerular crescents and RPGN based on management of other glomerulonephritides.¹⁸ One-quarter to one-half of patients have persistent renal dysfunction, and as many as 15% may progress to ESRD.^{89-91,93} Long-term prognosis is worse in patients with persistent proteinuria >1 g/dL after 6 months, and these patients should receive treatment with angiotensin-converting-enzyme inhibitors or angiotensin-receptor blockers.¹⁸ Other important causes of infection-related GN include cryoglobulinemic GN due to hepatitis C virus (HCV), hepatitis B virus (HBV), or human immunodeficiency virus (HIV) infection. Signs and symptoms of systemic disease may include palpable purpura, arthralgias or arthritis, and peripheral neuropathy.⁹⁴ Laboratory findings may include hypocomplementemia (especially undetectable C4), elevated rheumatoid factor (RF), circulating cryoglobulins, and positive viral serologies. Kidney biopsy demonstrates intraluminal thrombi on light microscopy with immunoglobulin and C3 deposition on immunohistology. Management of cases of rapidly progressive kidney disease may include plasma exchange, rituximab or cyclophosphamide, and antiviral therapy.⁹⁴⁻⁹⁶

IGA NEPHROPATHY

IgA nephropathy (IgAN) is an extremely common form of GN worldwide. It usually manifests in the second or third decade of life in North America and affects men twice as frequently as women.^{97,98} The majority of patients present with macroscopic hematuria coinciding with an upper respiratory tract or gastrointestinal infection. Patients may develop hypertension and varying degrees of proteinuria. Crescentic IgAN is associated with nephrotic-range proteinuria, severe hypertension, and rapidly declining renal function in less than 10% of cases.^{99,100} Severe AKI at initial presentation may also be caused by coincident

acute tubular necrosis due to macroscopic hematuria or crescentic disease. No specific serologic study to date can establish the diagnosis; renal biopsy is required. The severity of inflammation (e.g., crescents and capillary immune deposits, in addition to usual mesangial deposits), tubulointerstitial fibrosis, and glomerular sclerosis by light microscopy is variable but predictive of clinical outcomes. Immunofluorescence microscopy demonstrates mesangial IgA deposits.

The long-term prognosis of patients with IgA nephropathy is highly variable, but many patients develop progressive renal failure. Progression to ESRD is approximately 15% to 25% at 10 years and 25% to 30% at 20 years following diagnosis.¹⁰¹

Hypertension should be aggressively treated with angiotensin blockade and other agents if necessary.^{18,102} Patients with significant proteinuria (often defined as >0.5 to 1 g/dL) and declining renal function may benefit from corticosteroids or immunosuppressive agents. Corticosteroids appear to reduce the risk of progression to ESRD and decrease proteinuria in selected patients.¹⁰³⁻¹⁰⁷ Immunosuppressive medications such as cyclophosphamide or azathioprine should be reserved in rare cases of RPGN and crescentic GN.^{18,99,101} Predictors of disease progression include the degree of renal dysfunction at diagnosis, significant proteinuria, hypertension, and evidence of chronic disease by renal biopsy.^{97,98,108,109}

■ IGA VASCULITIS

IgA vasculitis (IgAV, formerly called Henoch-Schönlein purpura [HSP]) is indistinguishable from IgAN on kidney biopsy. However, IgAV is a systemic disease characterized by a palpable purpuric rash, arthritis or arthralgias, and gastrointestinal involvement. It occurs much more commonly in children than in adults. The classic presentation is sudden onset of rash, progressing from nonblanching erythematous macules to urticarial papules to purpura, with a symmetric distribution on the extensor surfaces of the distal extremities and buttocks.^{110,111} Children present more frequently with gastrointestinal manifestations and fever, whereas adults often have more severe renal involvement as well as joint symptoms.^{112,113} Renal involvement occurs in roughly one-third of children and two-thirds of adults.¹¹⁴ The most common manifestation is microscopic hematuria with or without RBC casts and nonnephrotic proteinuria.¹¹⁵

Renal involvement in IgAV is usually more severe at presentation than IgAN, but most children recover completely.^{112,116,117} Estimates of recovery and chronic kidney disease vary widely, but the prognosis for renal recovery is worse in adults. Poor prognostic indicators include renal dysfunction and significant proteinuria at presentation, hypertension, and extensive glomerular inflammation on histology.^{113,114,117,118} Treatment is primarily supportive, and trials to date do not support any specific treatment regimen.¹¹⁹ Conservative therapy is generally sufficient in most cases of IgA vasculitis. Patients with more severe skin, joint and/or gastrointestinal manifestations may benefit from a short course of oral corticosteroids. However, there is no clear evidence that prednisone prevents serious long-term renal disease.^{120,121} Intravenous corticosteroids may be required when there is severe abdominal pain and nausea that precludes oral therapy. Corticosteroid therapy is also indicated when there is severe crescentic disease accompanied by worsening kidney function.^{120,121} Kidney Disease Improving Global Outcomes (KDIGO) recommendations suggest that persistent IgAV be treated as isolated IgAN.¹⁸ There are limited reports on the use of plasmapheresis for the management of severe disease.^{122,123} Two adults with severe systemic manifestations refractory to corticosteroids and immunosuppressive agents were treated with plasmapheresis with subsequent improvement.¹²⁴

■ THROMBOTIC MICROANGIOPATHIES

Thrombotic microangiopathy (TMA) is characterized by widespread thrombosis of arterioles and capillaries, with intraluminal platelet aggregation and vessel wall thickening.¹²⁵⁻¹²⁷ The underlying pathophysiologic cause of TMA is endothelial damage caused by a variety

of insults. Primary TMA syndromes include thrombotic thrombocytopenic purpura (TTP), hereditary hemolytic uremic syndrome (HUS; Upshaw-Sculman syndrome), and primary atypical HUS. Secondary TMA syndromes include typical or diarrheal HUS (Shiga-toxin mediated), drug-induced syndromes, autoimmune disease (SLE, systemic sclerosis), pregnancy-related TMA (preeclampsia, eclampsia, and hemolysis, elevated liver enzymes, and a low platelet count [HELLP] syndrome), pancreatitis-related TTP/HUS, cancer and stem cell transplant-induced TTP/HUS, malignant hypertension, and infection-related TTP.

Clinical manifestations and laboratory findings of TTP and HUS overlap considerably. Therefore, patients presenting with microangiopathic hemolytic anemia and thrombocytopenia should be initially classified as having undifferentiated TMA or TTP-HUS. The classic pentad of findings in TTP includes microangiopathic hemolytic anemia, thrombocytopenia, neurologic symptoms and signs, impaired renal function, and fevers.^{125,127,128} However, all five manifestations are seen in less than one-third of patients. Neurologic symptoms may predominate, manifesting as confusion, headache, seizures, and coma. Renal manifestations are usually more prominent in HUS, and the typical presentation in children includes microangiopathic hemolytic anemia, thrombocytopenia, and AKI. Laboratory hallmarks include microangiopathic hemolytic anemia with schistocytes on peripheral smear, elevated lactate dehydrogenase levels, and thrombocytopenia, with platelet counts that are usually less than 60,000/ μ L.

Remarkable progress has been made in elucidating the molecular basis of TTP and HUS. TTP occurs in hereditary (Upshaw-Shulman syndrome) and acquired forms related to deficiency or the presence of antibodies that disrupt the function of the zinc metalloprotease ADAMTS13 (a disintegrin and metalloprotease with thrombospondin type 1 motif 13).¹²⁷⁻¹²⁹ This protein is involved in the cleavage of von Willebrand factor (vWF), and deficiency of ADAMTS13 leads to the accumulation of large multimers of vWF that bind platelets, leading to microvascular thrombosis. Historically, untreated TTP had a mortality rate of over 90%. However, mortality has fallen to 10% to 20% with the advent of treatment using plasma exchange.^{130,131} Other therapies include glucocorticoids, rituximab, and splenectomy in the case of refractory or relapsing disease.^{132,133} Hereditary forms require treatment with fresh frozen plasma or cryosupernatant that contains ADAMTS13. Since hereditary TTP is rare, acquired TTP is the presumed diagnosis in new cases.

Hemolytic uremic syndrome is the most common cause of AKI in children and presents with hemolytic anemia, thrombocytopenia, and AKI.^{125,134-136} The typical, or diarrheal, form of HUS (d-HUS) occurs most commonly following diarrheal infection with Shiga-toxin-producing *Escherichia coli* (*E. coli* O157:H7), which accounts for 90% of cases. The peak incidence occurs in children younger than 5 years of age. The illness begins with abdominal cramps and nonbloody diarrhea, followed by hemorrhagic diarrhea in 70% of patients. As the diarrheal illness is improving, patients develop severe renal failure, anemia, and thrombocytopenia. These children are often critically ill, and roughly one-half to two-thirds of patients require RRT. Hypovolemia is common, and rapid volume repletion is a critical component of early therapy. About 70% of patients will require RBC transfusions, and 25% will have neurologic involvement. Over the past few decades, mortality rates have fallen from roughly 40% to 50% to 3% to 5%, primarily due to aggressive supportive care with red blood cell transfusions and RRT as needed. Numerous therapies for HUS have been investigated without clear benefit, and treatment remains largely supportive. Antibiotic treatment of the diarrheal illness associated with *E. coli* O157:H7 is associated with increased risk of developing HUS. Spontaneous resolution occurs 1 to 3 weeks following disease onset, and the majority of patients demonstrate renal recovery. Unfortunately, some children develop ESRD, and up to 40% have long-term sequelae including chronic kidney disease, persistent proteinuria, and hypertension. Non-diarrheal-associated HUS occurs in a minority of patients and may be associated with other infections such as *Streptococcus pneumoniae*.

A small percentage of patients with HUS have sporadic or familial forms, known as atypical HUS. These patients have defects in the alternative complement pathway, and mutations have been described in complement factor H, complement factor I, and membrane cofactor protein.¹²⁷⁻¹²⁹ Mortality rates are highest in patients with complement factor H mutations, and most survivors progress to ESRD. Therapies with fresh frozen plasma, plasma exchange, and eculizumab, a monoclonal antibody targeting the terminal complement cascade, are under investigation for treatment of this devastating disease.¹³⁷ Eculizumab should be considered for patients with a presumptive diagnosis of atypical HUS based on the absence of features of secondary TMAs and failure to respond to 5 days of intensified plasma exchange.

An extensive variety of drugs have been associated with TMA. The pathophysiologic mechanisms underlying drug-induced TMA are not well understood, but immune-mediated effects or direct endothelial toxicity are likely important.¹³⁸ Immune-mediated TMA may occur when drugs induce the formation of antibodies that ultimately react with endothelial cells, platelets, and/or neutrophils and cause platelet microthrombi in addition to microvascular injury. The antibodies form when the drug or its active metabolites are present in the circulation or tissues. Once the drug is entirely cleared, no new antibody formation occurs.¹³⁹ Drugs associated with this phenomenon include quinine, gemcitabine, mitomycin C, quetiapine, and oxaliplatin.^{140,141}

Scleroderma renal crisis presents as acute kidney injury with abrupt onset of moderate to severe hypertension and may be accompanied by encephalopathy with seizures or flash pulmonary edema.¹⁴² A subset of patients may not be hypertensive but have blood pressures higher than baseline values, which purports a worse prognosis.¹⁴³ Roughly 10% of patients develop scleroderma renal crisis, usually occurring within 4 years of disease onset. The risk is greatest with diffuse cutaneous disease, and antecedent treatment with high-dose corticosteroids increases the risk of scleroderma renal crisis.^{144,145} Patients demonstrate microangiopathic hemolytic anemia, thrombocytopenia, proteinuria,

microscopic hematuria, and marked increases in plasma renin. In the past, untreated disease had a dismal prognosis, with less than 10% survival. The use of angiotensin-converting enzyme (ACE) inhibitors has revolutionized treatment; acute mortality rates are now below 25% with appropriate treatment.^{142,146,147} About one-half to two-thirds of patients will require RRT, but half of these patients recover enough renal function to become dialysis independent. Poor outcomes are associated with Cr above 3 mg/dL at the initiation of ACE-inhibitor therapy, dialysis dependence, poor blood pressure control, male sex, older age, and congestive heart failure. Patients with scleroderma renal crisis who do not require RRT have 90% survival rates at 5 years. In contrast, patients who become dialysis dependent have only 40% survival at 5 years. Early recognition and treatment are critical for both patient and renal outcomes. ACE inhibitors should be initiated rapidly and continued even if patients develop progressive renal failure or require RRT.

■ ANTIPHOSPHOLIPID SYNDROME

A small percentage of patients with antiphospholipid syndrome (APS) present with “catastrophic” APS, characterized by AKI and widespread small, and in some cases large, vessel venous and arterial thrombosis affecting multiple organs.¹⁴⁸ The disease progresses over days to weeks and commonly affects the kidneys, lungs, central nervous system, heart, and skin. The kidney is the most common organ affected, with renal involvement in over 70% of patients. Renal disease manifests as malignant hypertension and AKI, with 25% of patients requiring RRT. Mortality is estimated at 50%, and management includes treatment of the underlying cause (e.g., infection, SLE), high-dose corticosteroids (methylprednisolone, 500 g IV for 3 consecutive days, followed by prednisone, 1 mg/kg/day), systemic anticoagulation, plasma exchange to remove anticardiolipin antibodies, and intravenous immunoglobulin.¹⁴⁹

KEY POINTS

1. Many underlying causes for acute kidney injury (AKI) due to glomerulonephritis are reversible. Because the transition of active glomerular lesions to irreversible scar occurs rapidly, prompt diagnosis and early intervention are crucial.
2. Pulmonary renal syndromes constitute a medical emergency. Studies demonstrate that early aggressive treatment improves patient and renal survival.
3. Detailed histories and physical exams are important for distinguishing renal-limited disease from systemic diseases.
4. Initial evaluation should include basic chemistries, evaluation of the urine sediment, complete blood counts with review of the peripheral blood smear, assessment for proteinuria, and kidney ultrasound.
5. Serum complement levels are important tools for distinguishing causes of glomerulonephritis (GN): (a) normal serum complement

levels in most cases of IgA nephropathy, IgA vasculitis, ANCA-associated GN, and anti-GBM disease; and (b) depressed serum complement in immune complex GN including infection-related GN and lupus nephritis.

6. Depending on the clinical scenario, additional evaluations may include anti-neutrophil cytoplasmic antibodies (ANCA), anti-GBM antibodies, anti-nuclear antibodies (ANA), anti–double-stranded DNA (dsDNA) antibodies, serologies for streptococcal infection, viral serologies, and bacterial cultures.
7. The gold standard for diagnosis of glomerulonephritis remains kidney biopsy. However, critically ill patients are often at increased risk for complications, and it may be necessary to proceed with empiric treatment in the absence of biopsy in certain situations.

Acute interstitial nephritis (AIN) is an important cause of AKI characterized by inflammation of the renal interstitium and tubules. It is more properly called *acute tubulointerstitial nephritis* (Fig. 113-1). This disorder results from a hypersensitivity reaction most commonly induced by medications or infections. AIN may also result from autoimmune disorders including SLE, sarcoidosis, and Sjögren syndrome.^{1,2} AIN is seen in about 2% to 6% of kidney biopsy series, but the incidence may be as high as 25% in patients with unexplained AKI.^{1,3-5} Medications account for over two-thirds of cases. Many critically ill patients are treated with medications commonly associated with AIN, such as antibiotics, proton pump inhibitors, and diuretics (Table 113-1).^{6,7} It is important to recognize AIN early in order to identify inciting drugs that should be discontinued to minimize ongoing renal injury. Early improvement of kidney impairment and patchy infiltrates on biopsy indicate a more favorable prognosis.^{2,8} Poor prognostic indicators include advanced age, prolonged renal

FIGURE 113-1 ■ Acute interstitial nephritis. Diffuse, predominantly mononuclear cell infiltrate is present within an expanded and mildly edematous interstitium, and periodic acid–Schiff (PAS)-positive tubular basement membranes have wrinkling. Foci of tubulitis are also present (×200, PAS).

TABLE 113-1

Common Medications Associated with Acute Interstitial Nephritis

| |
|--|
| Antibiotics—penicillins, cephalosporins, sulfonamides, ciprofloxacin, rifampin |
| Anticonvulsants—phenytoin, carbamazepine, phenobarbital, valproate |
| Diuretics—thiazides, loop diuretics, triamterene |
| Herbal medications |
| NSAIDs |
| Proton-pump inhibitors |

impairment, and degree of chronic tubulointerstitial changes on kidney biopsy. Approximately 30% to 40% of patients will have some degree of long-term renal impairment.^{2,6,7}

Drug-induced AIN usually presents a few weeks following initiation of the medication but can occur after one dose in some cases. With removal of the offending agent, the duration of AKI can vary from a few weeks to months.^{1,2,7} The prototypical example of AIN is that of methicillin-associated AIN. The majority of patients with methicillin-induced AIN developed fevers, eosinophilia, pyuria, and hematuria a few weeks following exposure. About half of patients developed AKI for a duration of several weeks, followed by full recovery in 90%.⁶ Unfortunately, the classic triad of fever, rash, and eosinophilia occurs in only 10% to 15% of patients.^{1-3,6} Patients may present with mild renal impairment or severe AKI requiring RRT. The urine sediment may be bland or demonstrate sterile pyuria, leukocyte casts, and hematuria. In most cases, patients have subnephrotic-range proteinuria (<3 g/day), with a predominance of low molecular weight proteinuria, but two-thirds of patients with NSAID-induced AIN present with nephrotic syndrome.^{2,6} The diagnosis of AIN can be difficult, as systemic manifestations may mimic infection. Patients with pyelonephritis often have leukocyturia, hematuria, and mild proteinuria. Urine culture is essential to document infection, and sterile pyuria should prompt consideration of AIN as a diagnosis. AIN may be difficult to distinguish from acute tubular injury, particularly in patients with bland urinary sediments. Eosinophiluria, based on Wright or Hansel stain, is suggestive of acute AIN but is neither sensitive nor specific for this disorder.^{6,9,10} Eosinophiluria is also found in a variety of other disorders including pyelonephritis, cystitis, prostatitis, acute tubular necrosis, and crescentic and proliferative glomerulonephritis. As such, the significance of eosinophiluria must be carefully interpreted in the context of the entirety of the clinical picture. The absence of eosinophiluria does not exclude the diagnosis of AIN, making biopsy an important diagnostic tool to differentiate these entities and guide therapy.

The initial management of a patient with AIN is largely supportive, with dialysis as indicated. Removal of the suspected offending agent is the cornerstone of therapy. Identification of all candidate etiologic agents, elimination of potentially causative medications, and control of potential infectious causes are fundamental to the control of AIN.^{2,6} When replacing medications, it is important to choose medications that are not likely to cross-react with the original agent. The use of corticosteroid therapy remains controversial, and no large randomized trials have thoroughly examined the effectiveness of corticosteroid therapy in AIN.^{6,11} One small study in which the majority of patients developed AIN from antibiotics or NSAIDs demonstrated improved renal recovery with early steroid use.¹² Another study demonstrated that the majority of patients improved with medication withdrawal, but those patients who do not respond after a few weeks may subsequently benefit from corticosteroid administration.¹³ In another retrospective study in which over 90% of patients had drug-induced AIN and 60% received corticosteroids, there was no difference in renal outcome.⁴ MMF has been used successfully in 8 patients who were unable to taper off maintenance corticosteroids for AIN due to relapsing course.¹⁴

KEY POINTS

1. The diagnosis of acute tubulointerstitial nephritis (AIN) should be considered in patients with acute kidney injury and sterile pyuria or systemic manifestations of hypersensitivity, especially when temporally associated with infection or medication initiation.
2. Medications, particularly antibiotics, are responsible for over two-thirds of cases of AIN.
3. A definitive diagnosis of AIN can only be made with kidney biopsy.
4. Treatment of drug-induced AIN begins with discontinuation of the causative agent. Subsequent use of a causative agent may result in prolonged renal failure.

Antimicrobial stewardship is an important concept that is pertinent to virtually every clinician. Its goals are to combat the emergence of resistance, improve clinical outcomes, and decrease healthcare costs (Fig. 114-1).¹⁻⁷ In this chapter, we will focus on the advances in and obstacles to antimicrobial stewardship as outlined in Table 114-1 by breaking this discussion into two major areas: optimization of antimicrobial therapy and avoidance of unnecessary antibiotic administration.

OPTIMIZATION OF ANTIMICROBIAL THERAPY

Appropriate Antimicrobial Selection

Appropriate antibiotic therapy is the cornerstone of management in septic shock as well as in any serious infection requiring intensive care unit (ICU) care and has a great influence on hospital mortality. Appropriate antibiotic therapy is defined as an initial antimicrobial regimen that demonstrates *in vitro* activity against the isolated organism(s) responsible for the infection, while inappropriate antibiotic therapy is defined as an initial regimen demonstrating a lack of *in vitro* activity against the causative pathogen(s).⁸ The administration of inappropriate initial antibiotic therapy can lead to treatment failures and adverse outcomes.⁹⁻¹⁵ Similar associations between the administration of inappropriate initial antimicrobial therapy and greater mortality have been shown for bloodstream infections by *Candida*.¹⁶⁻¹⁸ Moreover, the importance of treating all pathogens associated with serious infection is further emphasized by a recent retrospective analysis of patients with severe sepsis and septic shock.¹⁹ For the entire cohort, the number needed to treat with appropriate antimicrobial therapy to prevent one patient death was 4.0 (95% confidence interval [CI], 3.7-4.3).

The importance of selecting appropriate initial antimicrobial therapy has been emphasized in the most recent Surviving Sepsis Guidelines.²⁰ The guidelines recommend that initial empiric anti-infective therapy include one or more drugs that have activity against all likely pathogens (bacterial and/or fungal or viral) and that the antibiotics penetrate, in adequate concentrations, into the tissues presumed to be the source of sepsis (grade 1B).²⁰ This guideline urges clinicians to utilize the patient's history, including drug intolerances, recent receipt of antibiotics, underlying disease, the clinical syndrome, and susceptibility patterns of pathogens in the community and hospital and that have been previously documented to colonize or infect the patient when making decisions regarding initial antimicrobial regimen selection.

Timing of Antibiotic Administration

In addition to selecting an appropriate antimicrobial regimen, the timing of antibiotic delivery is an essential element in determining the outcome of critically ill patients with infection. Several studies have found strong relationships between delays in effective antimicrobial initiation and in-hospital mortality for serious infections including ventilator-associated pneumonia (VAP) and septic shock.^{21,22} A recent meta-analysis of randomized and observational studies evaluating the

impact of goal-directed bundles on the outcomes of patients with septic shock found that timely antibiotic administration was statistically more common among patients receiving protocolized management of septic shock.²³ One of the studies in this meta-analysis was a prospective observational study that evaluated adult patients with severe sepsis from 77 ICUs in Spain.²⁴ Using a propensity-adjusted multivariate analysis, the authors identified early broad-spectrum antibiotic treatment to be associated with lower mortality. Members of the Surviving Sepsis Campaign subsequently performed a retrospective analysis of a large dataset collected prospectively from 165 ICUs in Europe, the United States, and South America.²⁵ In-hospital mortality was 29.7% for the cohort as a whole, and there was a statistically significant increase in the probability of death associated with the number of hours of delay for the first antibiotic administration.

Timely administration of effective antibiotics seems to be an important element in determining the outcome of critically ill patients. As discussed below, prediction tools for the presence of antibiotic resistance and rapid diagnostics may allow for a more rapid administration of appropriate therapy. However, emergency departments and ICUs should also ensure that they have processes in place to obtain and deliver antibiotic therapy expeditiously once the order for such therapy is received from the treating physicians.

Adequate Dosing of Antimicrobials and Pharmacokinetic/Pharmacodynamic Considerations

In addition to delivering timely appropriate antibiotic regimens, adequate drug concentrations at the site of infection are needed to optimize clinical outcomes. β -lactam and carbapenem antibiotics are time-dependent antimicrobials whose activities are primarily related to the duration the free drug concentration exceeds the pathogen minimum inhibitory concentration ($T_{\text{FREE}}/\text{MIC}$).²⁶⁻²⁸ Many factors influence the pharmacokinetics of antimicrobials in critically ill patients. Hypoalbuminemia, large-volume crystalloid administration, large pleural effusions or abdominal ascites, catecholamines, augmented renal clearance (ARC), and renal replacement therapies can all significantly alter infection site concentrations of administered antibiotics.²⁹

In VAP treatment, particularly for gram-negative bacteria (GNB), dose and duration of treatment might need to be augmented despite having selected an appropriate initial regimen. For instance, meta-analyses of tigecycline showed an increased mortality in nosocomial pneumonia, particularly VAP driven by GNB infections.³⁰⁻³² A randomized trial of patients with hospital-acquired pneumonia (HAP) found that tigecycline with or without ceftazidime had inferior cure rates to imipenem-cilastatin with or without vancomycin across all pathogens.³³ The hypothesis that the tigecycline dose (75 mg every 12 hours) was too low to achieve high enough concentrations above the MICs of pathogens prompted a higher dose study (100 mg every 12 hours) compared to imipenem-cilastatin.³⁴ Similarly, ceftobiprole, a cephalosporin with activity against MRSA and an extended GNB spectrum equivalent to ceftazidime or cefepime, was compared to linezolid and ceftazidime in patients with HAP/VAP.³⁵ Even though it achieved similar cure rates in patients with HAP, ceftobiprole was inferior to linezolid and ceftazidime in patients with VAP, in large part thought to be due to the underdosing of ceftobiprole in critically ill patients. This concern has led to a doubling of the dose of ceftolozone/tazobactam in the ongoing clinical registration trials of HAP/VAP.³⁶

TABLE 114-1

Antimicrobial Stewardship Program for the ICU Setting

1. Optimization of antimicrobial therapy
 - a. Appropriate antimicrobial selection
 - b. Timing of antibiotic administration
 - c. Adequate dosing of antimicrobials and PK/PD considerations
 - d. Duration of antibiotic treatment
 - e. Augmented renal clearance
 - f. Therapeutic drug monitoring
2. Avoidance of unnecessary antibiotic administration
 - a. Deescalation of empiric antibiotic regimen
 - b. Use of antibiotic resistance prediction tools
 - c. Biomarker guidance of antimicrobial therapy
 - d. Formalized antimicrobial stewardship programs
 - e. Rapid microbiological diagnostics

ICU, intensive care unit; PK/PD, pharmacokinetic/pharmacodynamic.

Critically ill patients display different pharmacokinetics; therefore, newer drug administration strategies for β -lactams and carbapenems have been investigated to include the use of prolonged infusions in order to optimize antibiotic delivery to infection sites. Even though observational studies showed better clinical cure with prolonged or continuous infusion, two meta-analyses have failed to confirm these findings.^{37,38} A subsequent meta-analysis that included 13 RCTs and 13 cohort studies, 12 of them focusing on nosocomial pneumonia, partially contradicted the previous meta-analysis findings.³⁹ Similar findings were observed in another recent meta-analysis demonstrating that administration of piperacillin-tazobactam or carbapenems by prolonged infusion, rather than by bolus administration, is associated with a lower mortality.⁴⁰ The results from the largest multicenter trial performed to date of prolonged antibiotic infusion in critically ill patients failed to demonstrate any mortality benefit.⁴¹

One of the best examples of the need for proper antibiotic dosing and drug exposure at the site of infection was recently demonstrated in a multicenter trial.⁴² These investigators aimed to determine whether β -lactam antibiotic dosing in critically ill patients achieves concentrations associated with maximal activity and whether antibiotic concentrations affect patient outcome. Of the 248 patients treated for infection, 16% did not achieve $T_{\text{FREE}}/\text{MIC}$ ratio greater than 1 at 50% of the dosing interval, and these patients were 32% less likely to have a positive clinical outcome. Positive clinical outcome was associated with a

$T_{\text{FREE}}/\text{MIC}$ ratio greater than 1 at both 50% and 100% of the dosing intervals. These data suggest that many critically ill patients experience adverse outcomes as a result of inadequate antibiotic exposure.

Duration of Antibiotic Therapy

For most critically ill patients, empiric antibiotic courses of 7 to 8 days of treatment should suffice, unless specific infections are identified, such as bacteremia, fungemia, endocarditis, osteomyelitis, or meningitis, which would require longer treatment durations. The data supporting the use of shorter courses of antibiotic therapy are probably strongest for VAP, depending on clinical severity, rapidity of clinical improvement, and most important, the underlying microbiology.⁴³⁻⁴⁶ The exceptions to shorter courses of antibiotic therapy in VAP are the difficulty to treat pathogens such as *Pseudomonas aeruginosa* and other nonfermenters that experience higher recurrence rates with shorter treatment regimens.⁴³ At least one randomized trial has found a greater mortality among patients with *P. aeruginosa* VAP receiving only 7 days of treatment.⁴⁷ Longer durations of treatment for nonfermenting GNB may be most important in situations where antibiotic exposure in the lung is limited by host factors such as increased volume of drug distribution and ARC.

The inflammatory biomarker procalcitonin has been shown to aid in limiting the duration of antibiotic exposure for patients with VAP as well as other types of infections.⁴⁸⁻⁵⁰ However, other clinical trials have failed to replicate these findings. A study performed in nine ICUs in Denmark enrolled 1200 critically ill patients to receive either the “standard-of-care-only,” receiving treatment according to the current international guidelines and blinded to procalcitonin levels, or the “procalcitonin arm,” in which current guidelines were supplemented with a drug-escalation algorithm and intensified diagnostics based on daily procalcitonin measurements.⁵¹ Although there was no mortality difference, length of stay in the ICU was increased by 1 day in the procalcitonin arm. A recent multicenter trial from Australia that enrolled 400 patients with suspected bacterial infection/sepsis also failed to demonstrate reductions in the overall median number of antibiotic treatment days with the use of procalcitonin.⁵²

In summary, clinicians should be aware that 7 to 8 days of therapy should suffice for empiric antibiotic therapy in most ICU patients. However, even shorter courses of empiric therapy should be used when the presence of infection is excluded, and longer treatment regimens may be required when dealing with specific host- and pathogen-related factors such as ARC, increased volume of distribution, and presence of infection with *P. aeruginosa* or other nonfermenters. It is probably most important to critically review all antibiotics on a daily basis to ensure that they are indeed necessary and, if so, that they are delivered in adequate concentrations.⁵³

Augmented Renal Clearance

ARC is defined as an 8-hour creatinine clearance more than or equal to 130 mL/min/1.73 m². At least one recent study has suggested that over 65% of ICU patients have ARC on at least one occasion during the first 7 days of their critical illness.⁵⁴ ARC has been linked with subtherapeutic β -lactam⁵⁵ and glycopeptide concentrations⁵⁶ as well as increased therapeutic failures in patients receiving antimicrobial therapy, resulting in adverse patient outcomes.^{42,57,58} One group of investigators has developed a scoring system to identify patients at high risk for ARC based on the following factors: age of 50 years or younger (6 points), trauma (3 points), and SOFA score of 4 or less (1 point).⁵⁹ A subsequent study found that the ARC score was 100% sensitive and 71.4% specific for detecting ARC.⁶⁰ Monte Carlo pharmacokinetic simulations demonstrated increased time at therapeutic antibiotic levels with the use of extended infusion dosing in the setting of ARC at drug cost savings of up to 66.7% over multiple intermittent dosing regimens. In addition to ARC, the use of renal replacement therapies can result in underexposure of antibiotics at the site of infection, requiring careful dosing adjustments.⁶¹

Therapeutic Drug Monitoring

Therapeutic drug monitoring (TDM) for β -lactams and carbapenems can be accomplished by several methodologies, allowing serum concentrations of antibiotics to be assessed in order to optimize delivery and minimize the occurrence of toxicity.^{62,63} However, the use of TDM for antibiotics other than vancomycin, aminoglycosides, and voriconazole has not become a routine or standard practice in most ICUs. Recent studies have demonstrated the ability of TDM to identify the need for antibiotic dosing adjustments in the setting of continuous renal replacement therapy due to excess serum antibiotic concentrations⁶⁴ as well as during treatment of MDR *P. aeruginosa* with fluctuating renal function.⁶⁵ Unfortunately, at the present time large variations exist in the types of β -lactams tested, the patients selected for TDM, drug assay methodologies, pharmacokinetic/pharmacodynamic targets, and dose adjustment strategies employed among critically ill patients.⁶⁶

AVOIDANCE OF UNNECESSARY ANTIBIOTIC ADMINISTRATION

Deescalation of Empiric Antibiotic Regimen

Antimicrobial deescalation is a clinical approach to empiric antibiotic therapy of serious infections that attempts to balance the need for appropriate initial therapy with the need to limit unnecessary antimicrobial exposure in order to curtail the emergence of resistance.⁵⁷ A deescalation approach usually requires initial combination antimicrobial treatment targeting nonfermenting GNB and methicillin-resistant *Staphylococcus aureus*.⁶⁸ However, depending on the clinical presentation, patient risk factors, and local epidemiology, other pathogens such as *Candida* species and *Clostridium difficile*, especially when diarrhea is present, may also need to be covered. Once the microbiological results are available and the patient's clinical response is observed, the antibiotic regimen can be narrowed based on the susceptibilities of the identified pathogens. Our local experience, as well as that of other groups, bears this out in demonstrating that the administration of appropriate initial antibiotic therapy with subsequent antimicrobial deescalation is associated with improved survival and shorter hospital stays.^{14,69-71} Moreover, local antibiotic deescalation guidelines have been able to successfully limit the use of broad-spectrum antibiotics targeting GNB in patients with skin and skin structure infections, representing an example of antimicrobial stewardship.^{72,73}

Computer decision support systems have also been employed to facilitate antimicrobial deescalation practices in the ICU setting. Thursky et al. employed a real-time microbiology browser and computerized decision support system for pathogen isolate-directed antibiotic prescription and found significant reductions in the proportion of patients prescribed carbapenems, third-generation cephalosporins, and vancomycin.⁷⁴ Similarly, our hospital has developed an automated decision-support system with real-time access to patients' prior antibiotic exposures and microbiological results.⁷⁵ Our experience with this system has shown that the use of inappropriate therapy can be reduced by almost 50% and that access to these data assist in the performance of timely deescalation.⁷⁵

Use of Antibiotic Resistance Prediction Tools

Knowledge of patient risk factors for the presence of infection with antibiotic-resistant pathogens should be a routine part of antibiotic decision making. For example, antibiotic-resistant pathogens are more commonly found in patients with community-acquired pneumonia (CAP) who have healthcare-associated risk factors (recent hospitalization, admission from a nursing home, or recent antibiotic treatment).^{76,77} However, a recent meta-analysis found that the current definition employed for healthcare-associated pneumonia (HCAP) did not accurately identify infections attributed to antibiotic-resistant

pathogens, providing further support for the use of more specific criteria to make this clinically important determination.⁷⁸

Shindo et al. demonstrated that independent risk factors for antibiotic-resistant bacteria occur in both patients diagnosed with CAP and HCAP including prior hospitalization, immunosuppression, previous antibiotic use, gastric acid-suppressive therapy, tube feeding, and nonambulatory status.⁷⁹ Another Japanese study prospectively applied a therapeutic algorithm based on the presence of risk factors for MDR pathogens in a multicenter cohort study of patients with CAP and HCAP.⁸⁰ These investigators found that MDR pathogens were more common in patients with HCAP than in those with CAP. However, it is not clear that clinicians can effectively apply such prediction tools prospectively in order to target broad-spectrum antibiotics to patients at greatest risk for antibiotic-resistant infections. This has served as the impetus for the development of rapid microbiological diagnostic tests to facilitate such decision making at the patient's bedside.

Clinical decision support systems represent one way of automating informatics data to include risk factors for antibiotic-resistant bacteria.^{74,75} Potential benefits derived from the use of such computerized systems include improvements in the efficiency and costs of existing stewardship programs, improvements in clinicians' knowledge regarding the treatment of infectious diseases, and improvements in pathogen prediction.⁸¹⁻⁸⁵ Thiel and colleagues demonstrated that the implementation of a standardized order set for patients with sepsis—that is currently automated and includes orders for antimicrobial therapy—resulted in more appropriate initial antimicrobial therapy and improved clinical outcomes in patients with severe sepsis and bacteremia.⁸⁶ Micek et al. designed an automated alert that provided feedback on prior antibiotic exposure and microbiological culture results in formulating current treatment approaches.⁷⁵ Based on clinical information available in the alert, 34 of 64 of the alerted patients who received inappropriate therapy (53.1%) could have received an alternative β -lactam antibiotic with in vitro susceptibility to the identified pathogen. These data suggest that an opportunity exists to employ hospital informatics systems to improve the identification of patients infected with antibiotic-resistant bacteria in order to prescribe more appropriate initial therapy.

Biomarker Guidance of Antibiotic Therapy

Procalcitonin has demonstrated utility, especially in the ambulatory setting, in guiding decisions regarding antimicrobial therapy.⁴⁸⁻⁵⁰ However, not all experiences with procalcitonin-guided decision making have shown reductions in duration of antibiotic exposure.^{51,52} A recent comprehensive literature review of procalcitonin-guided antibiotic management in critically ill patients found that the diagnostic value of serum procalcitonin concentrations to discriminate among systemic inflammatory response syndrome (SIRS), sepsis, severe sepsis, and septic shock was unestablished.⁸⁷ On the other hand, at least two meta-analyses suggest that procalcitonin guidance is used to shorten the duration of antimicrobial therapy in the ICU setting.^{88,89} The routine use of procalcitonin as an aid in antibiotic decision making should depend on whether a particular ICU has an already established culture of successful antimicrobial deescalation and stewardship.⁵³

The serum markers (1,3)- β -D-glucan and galactomannan have been used in identifying pathogens associated with invasive fungal infections to assist clinicians in guiding antifungal therapy. Based on their high negative predictive value in the appropriate clinical setting, the most suitable use of these markers seems to be in excluding the presence of invasive fungal infections.^{90,91} However, one study suggests that the use of (1,3)- β -D-glucan is the most rapid method for the identification of intraabdominal candidiasis in order to provide timely therapy in such patients.⁹² In addition, an investigation that measured galactomannan levels in BAL fluid obtained from ICU patients lends support to its use in pathogen identification and early treatment of pulmonary infection.⁹³ Nonetheless, a more recent study only showed modest agreement between galactomannan in BAL fluid and validated

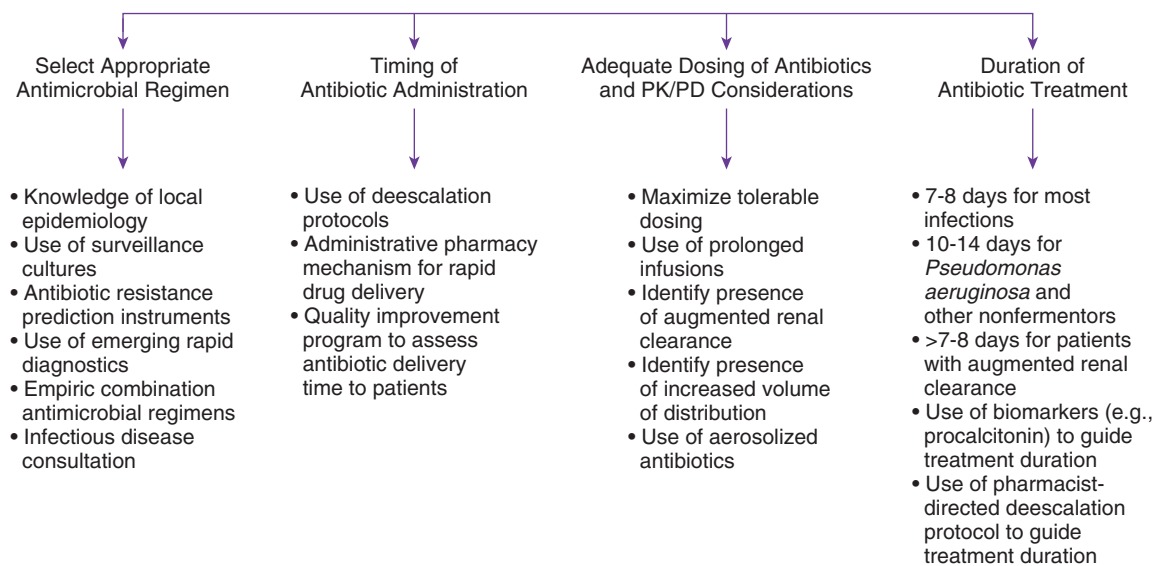

FIGURE 114-2 ■ Optimization of appropriate antimicrobial therapy as part of an antimicrobial stewardship program.

clinical diagnostic criteria for invasive fungal disease.⁹⁴ These markers of infection certainly have the potential to enhance stewardship—primarily through deescalation once a fungal infection has been excluded—and future clinical experience with these markers will determine if this potential can be fully realized.

Formalized Antimicrobial Stewardship Programs

Formally implemented antimicrobial stewardship programs (ASPs) have been associated not only with reduced infection rates but also with significant cost saving associated with reductions in the defined daily doses of antimicrobials targeted by the ASP.^{73,95,96} ASPs have been shown to increase the appropriateness of therapy for serious infections such as CAP as well as to increase the number of infectious disease consultations, which might also dramatically improve patient outcomes including mortality, hospital lengths of stay, and rates of readmission by providing a more precise antibiotic prescription.^{73,97-100} These attributes of ASPs account for why they are now recognized as mandatory components of hospital quality improvement efforts.

A recently updated meta-analysis of ASPs has solidified the benefits of these quality improvement initiatives.¹⁰¹ This meta-analysis found that ASPs could significantly result in less antimicrobial usage and reductions in *C. difficile* infections and colonization or infection with aminoglycoside- or cephalosporin-resistant GNB, methicillin-resistant *S. aureus*, and vancomycin-resistant *Enterococcus faecalis*.¹⁰¹ Additionally, more effective antibiotic prescribing practices for pneumonia due to the presence of an ASP were associated with a significant reduction in mortality, whereas practices aimed at decreasing excessive antibiotic prescribing were not associated with any significant increase in mortality.

Rapid Microbiological Diagnostics

Conventional microbiological procedures typically require several days for isolation, identification, and antimicrobial susceptibility testing of isolated bacteria from clinical samples including blood, respiratory tract, urine, and sterile site specimens. Recently, several molecular diagnostic platforms have been introduced and evaluated including the LightCycler SeptiFast Test (Roche, Basel, Switzerland), peptide nucleic acid fluorescence in situ hybridization (AdvanDx, Woburn,

MA), matrix-assisted laser desorption-ionization time-of-flight mass spectrometry (MALDI-TOF MS) (VITEK® MS, bioMérieux, Inc., Durham, NC), and DNA-based microarray platforms (Prove-it sepsis assay [Mobidiag, Keilaranta, Finland] and the Verigene Gram-Positive Blood Culture assay [Nanosphere, Northbrook, IL]).¹⁰² Additionally, automated microscopy methods such as the ID/AST system (Accelerate Diagnostics, Tucson, AZ) are in development, utilizing both genomic and phenotypic technologies to provide pathogen identification and antimicrobial susceptibilities in a rapid manner.¹⁰³

Huang et al. performed a quasi-experimental study to analyze the impact of MALDI-TOF MS in conjunction with an ASP in patients with bloodstream infections.¹⁰⁴ Use of MALDI-TOF MS significantly decreased time to organism identification and improved time to effective antibiotic therapy as well as optimal-directed antibiotic therapy. Mortality, length of ICU stay, and recurrent bacteremia were significantly lower during the intervention period. Similarly, the PCR-based GeneXpert MRSA/SA diagnostic platform (Cepheid, Sunnyvale, CA) was studied at the Veterans Affairs Medical Center in Houston, demonstrating that for methicillin-susceptible *S. aureus* bacteremia, the mean time to initiation of appropriate therapy decreased from 49.8 hours to 5.2 hours and the duration of unnecessary methicillin-resistant *S. aureus* drug therapy was reduced by 61 hours per patient.¹⁰⁵ It is expected that the clinical impact of rapid diagnostics will increase due to the enhanced ability of these methods to direct early appropriate treatment and avoidance of unnecessary antibiotic therapy.

CONCLUSION

Although antimicrobial therapy is frequently prescribed, clinicians should realize that these important therapeutic agents should be used wisely. Judicious use of antibiotics serves to combat the emergence of resistance, improve clinical outcomes, and decrease costs. Clinicians should realize the advances that have been made with regard to antimicrobial stewardship and utilize these tools, as well as future advances, to promote improved antimicrobial use. We are currently at a crossroads where antimicrobial stewardship offers us an opportunity to move forward in terms of enhancing the treatment of antibiotic-resistant infections for years to come (Fig. 114-2). ICU clinicians must be leaders in ensuring that their institutions have robust and effective ASPs.¹⁰⁶

KEY POINTS

1. All intensive care units should participate in active antimicrobial stewardship programs (ASPs) directed at optimizing the use of antimicrobials in critically ill patients.
2. The ASPs should focus on both optimizing the delivery of antimicrobial agents to infected patients and avoiding the unnecessary use of these agents.
3. Optimal antibiotic administration can be achieved by ensuring appropriate selection of drugs, timely administration of antibiotics, adequate dosing of these agents, avoidance of prolonged durations of therapy, and adjustments in delivery of drugs based on the physiology of critically ill patients (e.g., potential use of higher drug doses and/or prolonged infusions in the setting of augmented renal clearance and increased volume of distribution).
4. Minimizing the unnecessary use of antibiotics can be achieved with the use of deescalation strategies, use of antibiotic resistance prediction tools or biomarkers, and in the future, rapid diagnostics for pathogen detection and antimicrobial susceptibility.

Preventing pneumonia in the critically ill is a daunting task, and even controlling the incidence is difficult. Despite this challenge, many in the patient safety movement have suggested that nosocomial pneumonia should be a “never” event.^{1,2} While complete prevention of nosocomial pneumonia is unlikely,³ substantial progress has been made in reducing the incidence.⁴

Pneumonia is the most common nosocomial infection in the ICU.⁵ A large, 1-day point prevalence study of pneumonia demonstrated that nearly 10% of ICU patients were being treated for pneumonia.⁵ Post-operative patients, especially those undergoing cardiothoracic, neurosurgical, and trauma-related surgery, appear to have the highest rates.⁶ Coronary care unit patients appear to have the lowest rates; medical, respiratory, and other surgical patients demonstrate intermediate rates.

The influence of endotracheal intubation is so dominant that nosocomial pneumonia in the ICU has been almost synonymous with ventilator-associated pneumonia (VAP). Endotracheal intubation increases the rate of nosocomial pneumonia between 3- and 21-fold.⁷ Research on hospital-acquired pneumonia (HAP) has been dominated by VAP, and very little is known about pneumonia in nonintubated ICU patients. In addition, the role of both HAP and healthcare-associated pneumonia (HCAP)—pneumonia occurring in other healthcare settings, such as chronic ventilator facilities, inpatient rehabilitation units, and high acuity nursing homes—has been increasingly recognized. These ICU pneumonia cases are the cause of respiratory failure rather than a consequence of intubation as in VAP but with a frequency of multidrug-resistant (MDR) pathogens equivalent to that of VAP.⁸

Lack of diagnostic accuracy severely compromises efforts to prevent nosocomial pneumonia. Etiologic diagnosis is difficult in patients who are not intubated. Radiographic interpretation is also problematic. NNIS proposed an alternative definition of infectious ventilator-associated complications (IVAC) that does not require a chest radiograph to meet the definition.⁹ Multiple subsequent studies have demonstrated that the IVAC definition is neither sensitive nor specific and question the ability of VAP prevention strategies to alter the frequency of IVAC.¹⁰ Others ignore the need for abnormal chest radiographs and instead combine VAP with a newly defined ventilator-associated tracheobronchitis (VAT).¹¹⁻¹² Whether VAT is an early stage of VAP that progresses to VAP is still debatable.

A distinction should be made between prevention of all nosocomial pneumonia and prevention of life-threatening nosocomial pneumonia. The crude mortality rate for VAP ranges from 24% to 76%, with an estimated attributable mortality of 20% to 30%.^{7,13} The highest crude and attributable mortality rates are associated with typical late-onset MDR microorganisms such as *Pseudomonas aeruginosa*, *Acinetobacter* species, and methicillin-resistant *Staphylococcus aureus* (MRSA). Unfortunately, the most effective and well-documented strategies to prevent pneumonia work predominantly or exclusively in early-onset VAP and therefore have not resulted in a significant improvement in mortality. Conversely, one of the most consistent adverse effects of VAP (including early onset) is a prolonged duration of mechanical ventilation. Because duration of ICU stay is the principal determinant of cost of care, prevention measures may be cost-effective even if they do not result in improved mortality.

■ PATHOGENESIS

The key to prevention and control strategies is a clear understanding of the underlying pathogenesis of nosocomial pneumonia. The essence of nosocomial pneumonia pathogenesis involves three basic steps:

1. Colonization of the oropharynx with pathogenic microorganisms
2. Aspiration of oropharyngeal contents into the lower respiratory tract
3. Overwhelming of the host defense processes in the lower respiratory tract.

Effective prevention and control measures can be analyzed by their effect on one or more of these steps.

Despite the simplicity of this paradigm, assumption that the pathogenesis of all types of nosocomial pneumonia is the same would be naive and incorrect. An example is the role of gastric colonization preceding oropharyngeal colonization, the basis for attention to enteral feedings and stress ulcer prophylaxis in VAP prevention. Although possibly important for pneumonia due to Enterobacteriaceae, gastric and enteric colonization has no role in the pathogenesis of *S. aureus* or *P. aeruginosa* pneumonia, the two most common causes of VAP. Conversely, daily chlorhexidine baths did not prevent VAP in a trauma population but did significantly decrease VAP from MRSA.¹⁴ Therefore, prevention strategies should be individualized to the patients, pathogens, and processes prevalent in a specific ICU.

Colonization with Pathogenic Microorganisms

The major antecedent event to most nosocomial pneumonias is colonization of the oropharynx with pathogenic bacteria. The oropharynx is not sterile, but the character of the normal flora is remarkably constant. A variety of factors alter the normal flora, allowing replacement by more pathogenic microorganisms. The importance of the normal flora is illustrated by the adverse effects of iseganan, an antimicrobial peptide active against almost all bacteria. Iseganan treatment not only failed to decrease VAP rates but was associated with a trend toward increased mortality.¹⁵

Time of exposure to these selective forces is critical. Early-onset pneumonia, even early-onset VAP, tends to be caused by less pathogenic microorganisms such as streptococci, *Hemophilus influenzae*, and methicillin-sensitive *S. aureus*. Most selective forces are introduced in the hospital environment itself rather than specifically in the ICU. Therefore, patients who develop pneumonia during the first few days of ICU admission or mechanical ventilation are at risk for MDR pathogens if preceded by a 3- to 5-day hospital stay. Many of the same factors also operate in skilled-care nursing home facilities and have led to the designation of HCAP.

Previously, colonization of the oropharynx by gram-negative enteric bacilli, generally from the Enterobacteriaceae family, was emphasized. As part of the normal bowel flora, oropharyngeal colonization occurs by one of two main routes. The first is reflux of bacteria into the stomach from the duodenum, with subsequent gastroesophageal reflux into the esophagus and oropharynx. Colonization and proliferation in the stomach are critical intermediate steps in this pathway. Therefore, many prevention strategies logically target the stomach. The

other route is self-inoculation by the fecal-oral route, through contamination of equipment or the hands of health care providers or the patient.

The colonization pattern differs among many HAP/VAP pathogens. *S. aureus*, *P. aeruginosa*, and *Acinetobacter* species are common causes of VAP in many institutions. None of these microorganisms has a colonization pattern typical of Enterobacteriaceae. *S. aureus* normally colonizes the skin and the nasopharynx. Colonization of the oropharynx from the nose, especially with the use of nasogastric tubes in critically ill patients, can occur quite easily. Similarly, *Acinetobacter* is found on moist body surfaces and in the gingival crevices of patients with poor oral hygiene. *P. aeruginosa* is usually not part of normal bowel flora but is ubiquitous in the environment. One of the unique aspects of *Pseudomonas* VAP is the appearance of tracheal colonization before oropharyngeal colonization. Because colonization of the stomach is not an important intermediary step for these pathogens, the pneumonia they cause is unlikely to be affected by prevention measures directed at the stomach. Conversely, both MRSA and *Acinetobacter* colonization can be decreased with chlorhexidine whole-body bathing.¹⁴

Avoidance of Antibiotics

The single most important factor that leads to colonization of the oropharynx with pathogenic microorganisms is the use of systemic antibiotics, especially broad spectrum.¹⁶ Antibiotic killing of the usual oropharyngeal flora gives pathogens a selection advantage; at the same time, some pathogens are also eliminated. For this reason, antibiotics function more as amplifying agents rather than as true causes of colonization. The pathogenic microorganisms must still reside in the area normally, such as nasopharyngeal carriage of *S. aureus*, or be transferred from other sites, including the environment, to colonize. Thus, pneumonia can still occur despite avoidance of antibiotics. However, the causative microorganisms are more likely to be less virulent pathogens or even normal flora, such as α -hemolytic streptococci, and less likely to lead to life-threatening pneumonia.

Diagnostic strategies for fever in the ICU that result in the use of fewer antibiotics have been associated with lower mortality.¹⁷ Shorter courses and fewer antibiotics for documented infections in critically ill patients have also been associated with a decreased risk of superinfection.¹⁸⁻²⁰ Although avoiding antibiotics may have only a small effect on the risk of developing the first episode of pneumonia, limiting their use has a major effect on secondary pneumonia and infection-related death in the ICU.

Topical Antibacterial Agents. In contrast to systemic antibiotics, the use of topical antibiotics for the prevention of colonization may be beneficial. In general, strategies rely on controlling pathogenic microorganisms at specific sites, despite the effect on normal flora. Topical agents generally do not have the toxicity of systemic agents, and although the use of topical antibiotics can lead to MDR isolates, the risk may not be as great as with systemic antibiotics.

Selective Digestive Tract Decontamination (SDD). SDD is by far the most extensively studied and most aggressive topical antibiotic strategy to prevent colonization. Although the specific agents used in different studies vary, the major focus is on controlling oropharyngeal colonization by almost sterilizing the entire gastrointestinal tract, including the large bowel. SDD is discussed more extensively in Chapter 119. In summary, despite more than 40 randomized, controlled trials, the benefit of SDD remains unclear.

Topical Oropharyngeal Agents. Controlling colonization of the oropharynx alone has also generated interest, since little disruption of the normal bowel flora is expected by treating only the primary area of concern. Oropharyngeal decontamination alone appears to be equivalent to SDD for prevention of VAP.²¹ Chlorhexidine oral rinse has been the most extensively studied.²² Unfortunately, different concentrations of chlorhexidine have been used, and different populations have been compared. The strongest support for efficacy is for the 2% concentration. Chlorhexidine may not prevent infection with MDR pathogens such as *Pseudomonas* and *Acinetobacter*. Oral decontamination with

other agents, such as povidine/iodine and antimicrobial peptides,¹⁵ has not demonstrated benefit.

Recently interest in universal decolonization of patients with daily chlorhexidine for 5 days and nasopharyngeal mupirocin demonstrated lower bacteremia rates with MRSA and all pathogens.²³ No significant impact on MRSA pneumonia was demonstrated.

Aerosolized Antibiotics. The earliest studied form of topical colonization prevention was aerosolized antibiotics. In the early era of mechanical ventilation, daily aerosolized polymyxin B resulted in a dramatic decrease in the rate of gram-negative VAP.²⁴ Not surprisingly, routine use was soon complicated by the emergence of antibiotic-resistant microorganisms. This feature, combined with a lack of mortality benefit, led to abandonment of this strategy. In a recent study, aerosolized ceftazidime did not decrease VAP rates in trauma patients but also did not increase MDR pathogen colonization.²⁵ A recent variation of this practice is to use aerosolized antibiotics for purulent tracheobronchitis, thought to be a precursor to VAP.²⁶

Avoidance of Increased Gastric pH

The normally acidic environment of the gastric lumen is extremely effective in preventing colonization with either swallowed oropharyngeal flora or refluxed enteric flora. Several prevention strategies focus on this aspect of prevention.

Stress-Ulcer Prophylaxis. Because gastrointestinal bleeding from stress ulceration was at one time a substantial problem in ventilated patients and a major cause of death, prophylaxis against stress ulceration was considered critical for ventilated patients. However, the incidence of stress mucosal ulceration has decreased markedly as a result of better hemodynamic resuscitation, improved ventilatory strategies, and earlier use of enteral nutrition.

The debate regarding the optimal gastrointestinal bleeding prophylaxis has therefore evolved over the past few decades. Initially, antacids were found to be inferior to histamine type 2 blockers (H_2 blockers). In addition to increasing gastric pH, antacids increase gastric volume, which is probably an independent risk factor for VAP. Subsequently, sucralfate was hypothesized to be superior to H_2 blockers because it does not affect gastric pH and might have intrinsic antibacterial properties. No clear-cut benefit of sucralfate over H_2 blockers in reducing VAP has been found, while a slight but consistent increase in gastrointestinal bleeding has been documented.²⁷ Proton pump inhibitors (PPIs) appear equivalent to H_2 blockers.

A more important issue is whether stress-ulcer prophylaxis is needed at all in most mechanically ventilated patients. The few placebo-controlled trials suggest that H_2 blockers and sucralfate may lead to an increased risk of VAP compared with controls. Several multivariate analyses found PPIs associated with increased pneumonia rates, including HAP/VAP,^{28,29} HCAP, and even community-acquired pneumonia.³⁰ A subgroup of patients at increased risk for gastrointestinal hemorrhage can be identified, and patients without these high-risk factors may not need prophylaxis.

Enteral Nutrition Strategies. Malnutrition is clearly associated with an increased risk of pneumonia and increased mortality in the critically ill. In addition to classic effects on cell-mediated immunity, an effect specific to pneumonia is increased binding of gram-negative bacilli, including *Pseudomonas*, to epithelial cells.³¹

Enteral administration of nutrition is the preferred route for treating and preventing malnutrition in the critically ill, although parenteral nutrition in high-risk patients is preferable to no nutrition.³² Meta-analysis has suggested that patients can even be fed soon after gastrointestinal surgery.³³ However, continuous enteral nutrition infusions may increase both gastric pH and gastric volume, increasing VAP risk.^{34,35} A randomized trial found that the risk of VAP was increased with early aggressive feedings compared with low-level enteral nutrition (approximately 20% of goal feeding rate).³⁶ The lower rate was chosen to avoid atrophy of the microvilli of the enteric mucosa, a potential source of nosocomial infection. The increased risk of VAP was attributed to an increased risk of aspiration, which is also seen in surgical series.³³ However, meta-analysis of early versus delayed enteral

nutrition suggests a mortality benefit and probable decreased risk of VAP with early feedings.³⁷ A balance between potential risks would be early initiation of enteral feeding but avoidance of aggressive infusions that might cause high gastric residuals and gastric distention. Neither bolus feedings³⁸ nor acidification of enteral feedings³⁹ improved VAP rates but were associated with increased adverse events.

Modified Endotracheal Tubes

Bacteria can adhere to the polyvinyl chloride surface of endotracheal tubes through secretion of a glycocalyx. Protected from systemic antibiotics and host defense processes, microorganisms in this glycocalyx can become a source of reinoculation of the lower respiratory tract. This mechanism may explain the high rates of recurrent VAP, particularly for *Pseudomonas*. A silver-impregnated endotracheal tube demonstrated a lower incidence of VAP and a delay in onset in those who do develop VAP,⁴⁰ although cost remains a barrier to routine use.

Cross-Infection

The role of cross-contamination in the ICU should never be underestimated. Cross-contamination can cause colonization with specific pathogenic bacteria in a patient who has no other risk factors for that microorganism. In particular, *P. aeruginosa* and MRSA appear to have the greatest potential to cause cross-contamination and subsequent infection.

By far the most important factor in cross-infection is hand washing among caregivers. Multiple studies document poor infection control practices of medical personnel, including physicians and bedside nurses. The risk of inadequate hand washing increases with the intensity of care needed for an individual patient and with the number of patients per nurse.⁴¹ Use of an alcohol-based, self-drying hand wash appears to be effective and to increase compliance with hand washing.⁴² Routine decolonizing also appears to decrease rates of cross-infection.²³

Avoiding cross-contamination via medical equipment is also important. Contaminated equipment remains a major cause of epidemic outbreaks of nosocomial pneumonia. Any clustering of VAP, especially when caused by an unusual agent, should raise this possibility. Respiratory therapy equipment is particularly suspect, and adherence to standards for the sterilization of ventilators, bronchoscopes, and other reusable equipment should be rigorous.

Probably the best prevention strategy is a continuous, multifaceted, multidisciplinary program of infection control.⁴³ An important component of this program is monitoring VAP rates and providing feedback to individual units on their infection rates. Although such a program is costly to develop, the substantial cost-benefit of avoiding pneumonia usually justifies the expense.

Aspiration

The role of aspiration in nosocomial pneumonia is probably the least controversial. Evidence from a variety of sources documents the importance of aspiration, although the definition varies.

Large-Volume Aspiration

Large-volume aspiration is clearly a risk factor in nonintubated ICU patients. Predisposing factors for this type of aspiration are gastrointestinal, such as protracted vomiting from bowel obstruction or gastrointestinal bleeding, and neurologic, including seizures, induction of anesthesia, and alcohol intoxication. Appropriate use of endotracheal intubation is actually a protective factor for this type of aspiration. If large-volume aspiration has occurred, selective use of bronchoscopy to extract solid material that might occlude a bronchus and cause post-obstructive pneumonia may be of benefit. Empirical antibiotics, especially prolonged courses, do not clearly prevent pneumonia but do select for more virulent microorganisms.

Small-Volume Aspiration

Aspiration of a smaller volume of secretions is also associated with pneumonia in both intubated and nonintubated patients. Neurologic

disease with an inability to protect the upper airway is consistently documented as a risk factor for pneumonia. In this situation, aspiration occurs before or in conjunction with endotracheal intubation. A large inoculum of oropharyngeal flora reaches the lower respiratory tract, and clinical pneumonia usually occurs within 48 to 72 hours. High levels of amylase in BAL fluid is a marker of this risk.⁴⁴

Prevention of pneumonia from small-volume aspiration is probably best achieved by prophylactic antibiotics. Prospective observational studies suggest that antibiotics early in the course of mechanical ventilation are associated with a lower incidence of pneumonia.³⁴ However, the best evidence is a prospective, randomized trial of short-course cephalosporin prophylaxis (two doses) in patients intubated for non-traumatic coma.⁴⁵ The incidence of VAP was only 23% in the prophylaxis group, compared with 66% in the control group. These findings are corroborated by a before/after quality improvement study⁴⁶ and by the many SDD studies reporting a decreased incidence of pneumonia when a short course of systemic antibiotics was included with the topical antibiotics. Prophylactic antibiotics are effective only in the initial intubation of patients not previously hospitalized for a significant period and is dependent on the aspirated bolus containing mainly normal oral flora rather than MDR pathogens.

This prevention strategy seems to contradict the importance of avoiding unnecessary antibiotics discussed earlier. Two aspects outweigh the potential downside of increased risk of oropharyngeal colonization with more pathogenic bacteria. First, antibiotics are continued for only 24 hours. Second, the 40% lower risk of pneumonia in patients given prophylaxis avoids a subsequent longer course of antibiotics, often with a wider spectrum.

Microaspiration

Microaspiration is by far the most important form of aspiration in intubated patients. Oropharyngeal secretions pool above the cuff of the endotracheal tube in most intubated patients. Extremely small volumes of secretions can pass below the cuff during small movements of the endotracheal tube associated with head repositioning, coughing, and other activities. Up to 45% of patients have abundant aspiration in the first 48 hours post intubation.⁴⁷ Because oropharyngeal secretions contain 10^6 to 10^{10} bacteria/mL, even secretions of 0.1 mL can present a significant infectious challenge to the host defenses of the lower respiratory tract.

Shorter Duration of Endotracheal Intubation. The risk of VAP is not linear; the greatest risk occurs early, with subsequent tapering in frequency with each week. In addition, early-onset VAP (within 5-7 days of intubation) has the lowest attributable mortality. Therefore, the sooner the patient is extubated, the lower the cumulative risk of pneumonia and the lower the risk of lethal nosocomial pneumonia.

The best strategy is avoiding intubation completely. Management of many patients with noninvasive ventilation (NIV) is now standard practice in most ICUs. However, patients who fail NIV appear to have an increased duration of subsequent endotracheal intubation and thus an increased risk of VAP. Careful selection of candidates for NIV and early abandonment in unsuccessful cases are critical to decreasing the pneumonia risk.

Even when patients are intubated, variations in duration of mechanical ventilation for the same type and severity of critical illness suggest that efforts to shorten the duration are a viable approach to prevent VAP. Several protocolized strategies demonstrate significant benefits, including daily interruption of sedation and assessment of ability to wean.⁴⁸

The downside of an aggressive extubation strategy is the association between reintubation and a three-fold increase in risk of VAP.⁴⁹ Reintubation reexposes the patient to the risk of small-volume aspiration. In addition, colonization of the oropharyngeal secretions by more pathogenic bacteria is more likely because of the prior episode of intubation and short-course antibiotics will not have the same beneficial effect. Therefore, although avoiding or shortening the duration of mechanical ventilation is clearly a laudable goal, an increase in the risk of VAP may occur with an overly aggressive approach.

Avoidance of Ventilator Tubing Manipulation. Condensation of exhaled gas in the expiratory limb of the tubing or from humidifiers in the inspiratory limb can become heavily colonized with bacteria. Instillation of this liquid bolus into the patient's airway during manipulation of the tubing or movement of the patient can present a significant bacterial challenge to lower respiratory tract defense. The most consistent evidence that ventilator tube manipulation increases the risk of VAP is that increasing the interval between ventilator tubing changes decreases the incidence of VAP. Most institutions no longer change ventilator tubing unless gross contamination is present.

Meta-analysis of eight randomized controlled trials of heat and moisture exchangers (HMEs) rather than heater-humidifiers suggested a 30% reduction in VAP rates, especially if the patient was ventilated for more than 7 days.⁵⁰ Increased rates of endotracheal tube occlusion secondary to inspissated secretions with the use of HMEs and other considerations, especially cost, determine the frequency of their use.

Transporting ventilated patients outside the ICU, usually for diagnostic procedures, is also associated with an increased risk of VAP. In a prospective study, 24% of patients requiring transport outside of the ICU developed VAP, compared with only 4% of patients who did not.⁵¹ More than half of ventilated patients required transport at least once. Need for ambu bagging, changing ventilators, moving the patient out of bed, and other aspects of the process all increase the possibility of inadvertent introduction of ventilator tubing condensate into the patient. In addition, unintentional extubation is greater when transferring ventilated patients.

Maintenance of Artificial Airway Cuff Pressure. Adequate pressure (generally ≥ 25 cm H₂O) to maintain a seal around the cuff of artificial airways is critical to prevent microaspiration. Maintaining continuous control of tracheal cuff pressure resulted in a decrease in VAP incidence from 22 to 9.7 confirmed cases/1000 ventilator days.⁴⁷ Maintenance of cuff pressures may also decrease proximal airway secretions, the hallmark for the diagnosis of VAT.²⁶ The addition of low levels of positive end expiratory pressure (PEEP) has been associated with decreased aspiration and risk of VAP, possibly due to the greater attention to tracheal cuff pressures required in patients on PEEP. Inattention to tracheal cuff pressure obviates the benefit of other interventions, such as continuous aspiration of subglottic secretions (CASS).⁵²

Modified Endotracheal Tubes. A variety of modifications of the endotracheal tube itself have been designed to decrease microaspiration. Most attempt to minimize longitudinal folds in standard tracheal tube cuffs by changing the type of material or the shape of the cuff. No significant difference in VAP rates has been found in tapered versus cylindrical or polyurethane versus polyvinyl chloride cuffs.⁵³

An endotracheal tube that allows continuous aspiration of subglottic secretions (CASS) pooled above the endotracheal tube cuff has been extensively studied. The extra channel with a lumen on the dorsal surface, just above the level of the inflatable cuff, allows aspiration of secretions pooled above the cuff. One clinical practice guideline found the greatest level of evidence for VAP prevention was CASS.⁵⁴ Studies of CASS have variably demonstrated lower VAP rates but mainly in early-onset VAP: no decrease in VAP due to MDR microorganisms and no mortality differences have been demonstrated. The benefit of CASS is obviated if the patient receives antibiotics early in the course of mechanical ventilation, and pneumonia can also occur if the system malfunctions, usually caused by plugging of the lumen or low cuff pressures, allowing secretions to drain into the distal trachea rather than collecting above the cuff. These factors and the high cost have limited the use of this modality.

Early Tracheostomy. Tracheostomy has potential benefits for VAP prevention: the glottis is not held open by the endotracheal tube and the vocal cords can be opposed, decreasing the risk of aspiration significantly. The security of a tracheostomy may allow greater mobilization and a greater amount of time spent in the upright position, also decreasing aspiration. Routine tracheostomy may be one explanation for the leveling off of VAP incidence after several weeks of mechanical ventilation. The benefit of early tracheostomy remains unsettled.⁵⁵

Technique may also matter, with tracheostomy performed by the percutaneous dilatational technique more beneficial.⁵⁶

Semirecumbent Positioning. The degree of gastroesophageal reflux is significantly greater in supine patients than in semirecumbent patients.⁵⁷ Not only is reflux greater, but bowel flora were found to colonize the oropharynx and bronchial tree in 68% of patients ventilated in the supine position, compared with only 32% in the semirecumbent position. A prospective, randomized trial clearly demonstrated that both clinically suspected and microbiologically confirmed cases of VAP were more common in patients ventilated in the supine position (8% of clinically suspected VAPs vs. 34% for semirecumbent).³⁵ Supine body position (odds ratio 6.8) and enteral nutrition (odds ratio 5.7) were both independent risk factors for VAP, with the highest frequency in patients receiving enteral nutrition in the supine position (50%).

Avoiding the supine position as much as possible is a simple and effective preventive measure that should be practiced in all ICUs.⁵⁴ However, compliance with elevation of the head of the bed to 45° is difficult, and smaller degrees of elevation are not associated with decreased VAP rates.⁵⁸ In patients unable to be placed in the semirecumbent position, continuous lateral rotation with specialized beds may be beneficial.⁵⁹

Avoidance of Gastric Overdistention. Even in a semirecumbent position, many patients still have gastroesophageal reflux and microaspiration when given enteral feedings. The major issue of overdistention of the stomach can be addressed several ways. The first is use of nasogastric tubes rather than nasogastric tubes. Although attractive theoretically, meta-analysis of eleven randomized, controlled trials did not show a VAP prevention benefit of postpyloric feeding compared with gastric feeding.⁶⁰ The major limitation is the difficulty placing postpyloric tubes.

A second strategy is the use of gastric prokinetic agents such as metoclopramide. An additional benefit of these agents is increased tone of the lower esophageal sphincter, which potentially decreases the risk of reflux while increasing gastric emptying. Once again, a randomized, controlled trial failed to confirm the benefit of using this agent to decrease the risk of VAP.²⁹

Overwhelming Lower Respiratory Host Defenses

An underappreciated fact regarding nosocomial pneumonia is that despite the extremely common occurrence of aspiration of oropharyngeal secretions containing pathogenic bacteria, only a minority of colonized patients actually develop pneumonia. In the classic study by Johanson et al., only 23% of patients with gram-negative colonization of the oropharynx subsequently developed pneumonia.⁶¹ Others have shown that quantitative culture levels of microorganisms equivalent to those found in pneumonia can transiently appear in routine non-bronchoscopic BAL samples without causing clinical VAP.⁶² Thus, the two steps described earlier—colonization by pathogens and aspiration—are necessary but not sufficient causes of nosocomial pneumonia.

The third step in the pathogenesis of nosocomial pneumonia, overwhelming the lower respiratory tract defenses, is the least studied or understood. A major reason for this lack of understanding may be that the causes are heterogeneous and patient dependent, in contrast to the stereotypical steps of colonization and aspiration. As infection control and patient safety efforts become more effective, the remaining patients who develop VAP are even more likely to have significant defects in lower respiratory tract host defense. Patients who develop VAP should generally be considered to have a form of acquired immunosuppression. The more frequent occurrence of other nosocomial infections in patients with VAP supports this concept. In addition, some VAP patients develop multiple separate episodes of VAP, suggesting disproportionate compromise of lower respiratory tract defenses.

Many of the causes of compromised lower respiratory tract defenses involve underlying disease or critical illness, precipitating ICU

admission and the need for mechanical ventilation. However, several risks generic to most ICU patients may be targets for prevention.

Minimizing Antibiotic Use

Rather than being sterile, lung alveoli harbor a normal bacterial flora. This recognition raises important issues in understanding the development of HAP/VAP. The normal lung microbiome is similar to that of the normal oropharynx, predominantly streptococci but also anaerobes, *Hemophilus*, and *Mycoplasma*, but at significantly lower concentrations.⁶³ This normal alveolar flora therefore represents an important component of host defense that, similar to that of the oropharynx and the gastrointestinal tract, is adversely affected by systemic antibiotics. *Pseudomonas* pneumonia is virtually never seen without previous antibiotic exposure and develops with progressive monolithic replacement of the normal heterogeneous lung microbiome in response to antibiotic pressure.⁶⁴ Minimizing the effect of antibiotics on VAP may occur with enteral probiotics,⁶⁵ but lung-specific therapy is not available. Diagnostic strategies for VAP that result in less antibiotic treatment^{17,20} and earlier discontinuation in culture-negative patients⁶⁶ have consistently resulted in improved mortality and less superinfection.

Corticosteroids

Systemic corticosteroids have well-documented antiinflammatory effects that can influence immune function. The difficulty in determining the effect of corticosteroids on risk of VAP is the competing beneficial effect on other risk factors for VAP. An example is that the use of corticosteroids may allow earlier extubation of a patient intubated for an exacerbation of asthma, thereby lowering the risk of VAP. This dual effect probably holds true for most cases in which corticosteroids are used acutely for critically ill patients. The potential benefits begin to be outweighed by adverse consequences after more prolonged courses.

Transfusions

A common cause of immunosuppression is red blood cell transfusions. This effect of transfusions has been known for decades and was used therapeutically in the past for pretransplantation management of patients with end-stage renal disease. The transfusion trigger varies widely among institutions and even among individual practitioners. A conservative transfusion policy was reported to be associated with equivalent mortality to more liberal transfusions in most ICU patients⁶⁷ and decreased VAP rates in trauma patients.⁶⁸

KEY POINTS

1. A distinction should be made between the prevention of all nosocomial pneumonia and the prevention of **life-threatening nosocomial pneumonia, usually late-onset ventilator-associated pneumonia.**
2. **Pathogenesis of nosocomial pneumonia can be broken down into three basic steps:** colonization of the oropharynx with pathogenic microorganisms, aspiration, and overwhelming of the lower respiratory tract's host defense processes.
3. The most important factor in colonization of the oropharynx with pathogenic microorganisms and compromise of distal lung defenses is the suppression of normal flora at these sites **by systemic antibiotics, especially broad-spectrum antibiotics.**
4. The risk of ventilator-associated pneumonia is time dependent, so **any maneuver that decreases the duration of mechanical ventilation will decrease pneumonia rates.**
5. **Avoiding the supine position** as much as possible in ventilated patients **and maintaining adequate tracheal cuff pressure** are simple and effective measures to prevent microaspiration and should be practiced in all ICUs.
6. Several lines of evidence suggest that **minimizing the number of manipulations of the ventilator tubing** will decrease the incidence of ventilator-associated pneumonia.
7. **Causes of the relative immunocompromise** that allows bacteria to overwhelm local host defenses in the lung are heterogeneous and patient dependent, unlike the stereotypical steps of colonization and aspiration.

ANNOTATED REFERENCES

- Drakulovic MB, Torres A, Bauer TT, et al: Supine body position as a risk factor for nosocomial pneumonia in mechanically ventilated patients: a randomised trial. *Lancet* 1999;354:1851-1858.
This randomized, controlled trial of body positioning clearly demonstrates a decreased risk with the semirecumbent position, providing strong evidence of the role of microaspiration in the pathogenesis of VAP.
- Girard TD, Kress JB, Fuchs BD, et al: Efficacy and safety of a paired sedation and ventilator weaning protocol for mechanically ventilated patients in intensive care (Awakening and Breathing Controlled trial): a randomised controlled trial. *Lancet* 2008;371:126-134.
The combination of daily awakening from sedation and spontaneous breathing trials resulted in earlier extubation, shorter ICU length of stay, and lower mortality than the group with attempts at spontaneous breathing trials without specified sedation holds.
- Nseir S, Zerimech F, Fournier C, et al: Continuous control of tracheal cuff pressure and microaspiration of gastric contents in critically ill patients. *Am J Respir Crit Care Med* 2011;184:1041-1047.
This study illustrates the significant number of intubated patients with microaspiration and demonstrates the benefit of continuous maintenance of tracheal cuff pressure on both suspected and confirmed VAP.
- Sirvent JM, Torres A, El Ebiary M, et al: Protective effect of intravenously administered cefuroxime against nosocomial pneumonia in patients with structural coma. *Am J Respir Crit Care Med* 1997;155:1729-1734.
Randomized, controlled trial of true prophylactic antibiotic use to prevent VAP in a defined subgroup illustrates the two-edged sword of antibiotics—decreasing the risk of early pneumonia while selecting for more pathogenic microorganisms and possibly increasing the risk of late-onset VAP.
- Valles J, Artigas A, Rello J, et al: Continuous aspiration of subglottic secretions in preventing ventilator-associated pneumonia. *Ann Intern Med* 1995;122:179-186.
Randomized trial demonstrating the decreased risk of early-onset VAP with a manipulation that decreases the amount of microaspiration. This study illustrates the problem of secretions pooling above the cuff of the endotracheal tube and its role in VAP, even if the practical use of continuous aspiration of subglottic secretions is limited.

In critical care settings, antibiotics commonly used to treat gram-negative infection include β -lactams (penicillin, cephalosporin, carbapenem, and monobactam), fluoroquinolones, and aminoglycosides. Combinations of a β -lactam with aminoglycoside or fluoroquinolone are used to overcome bacterial resistance and to provide synergistic activity. A short discussion of polymyxins is included for the treatment of resistant gram-negative pathogens.

■ β -LACTAMS

Mechanism of Action

β -lactam antibiotics exhibit their bactericidal effects by inhibiting cell wall synthesis. The primary function of the bacterial cell wall is to maintain cell shape and to protect the organism from osmotic rupture. Peptidoglycan, the essential component of the cell wall, is composed of alternating *N*-acetylglucosamine (NAG) and *N*-acetylmuramic acid (NAM) cross-linked by peptide side chains.¹ β -lactam antibiotics are structural analogs of D-alanyl-D-alanine of the peptide side chain. Acylation of penicillin binding protein transpeptidase enzymes (PBPs) results in inhibition of peptidoglycan formation and consequent bacteriolysis and death.^{1,2}

The efficacy of a β -lactam antibiotic is determined by its ability to reach the target PBPs and its binding affinity to various PBPs.³ In gram-negative bacteria, the peptidoglycan lies in the periplasmic space, and the outer membrane functions as a permeability barrier to substrates. β -lactams are hydrophilic molecules and must cross the outer membrane via porin channels to reach PBPs.⁴ Entry through the porin channels is determined by size, charge, and hydrophobicity.^{1,5} In contrast, in gram-positive bacteria, peptidoglycan is the outermost structure of the cell, conferring easier access to β -lactam antibiotics.

Resistance

Four primary mechanisms allow bacteria to resist the cytotoxic activity of β -lactams. First, modification of PBPs can decrease their binding affinity for β -lactams. This mechanism is largely used by gram-positive bacteria, although it is important in some gram-negative bacteria, including *Haemophilus influenzae* and *Neisseria meningitidis*.⁶⁻⁹ Second, deficiency or loss of outer membrane proteins in gram-negative bacteria can diminish the permeability of the membrane to β -lactam and thus restrict its access to PBPs. Down regulation of OprD is associated with *Pseudomonas aeruginosa* resistance to imipenem^{10,11} and the loss of CarO associated with carbapenem resistance in multidrug-resistant *Acinetobacter baumannii*.^{12,13} Third, active efflux systems, especially in conjunction with decreased outer membrane permeability, can result in multidrug resistance in gram-negative bacteria. Overexpression of the MexAB-OprM efflux pumps in *P. aeruginosa* confers intrinsic resistance to multidrugs, including β -lactams.^{14,15} *A. baumannii* showing upregulated AdeABC efflux pump is associated with a higher level of resistance to β -lactams including carbapenems.¹⁶ Finally, β -lactamase production is largely responsible for β -lactam antibiotic resistance among gram-negative bacteria in the critical care setting. β -lactamase contains either a serine residue or a metal ion to acylate

and hydrolyze the β -lactam ring, rendering the drug inactive.⁹ β -lactamase can be encoded either chromosomally or via plasmids or transposons. β -lactamase production may be constitutive or inducible, and β -lactam antibiotics vary in their ability to induce β -lactamase production.^{17,18}

Extended-spectrum β -lactamases (ESBLs) have been found in Enterobacteriaceae, most commonly in *Klebsiella pneumoniae*, *Escherichia coli*, and *Enterobacter* species. These ESBLs hydrolyze third-generation cephalosporins and aztreonam but are inhibited by β -lactamase inhibitors.¹⁹ Numerous studies report outbreaks of ESBL-producing *Klebsiella* and *Enterobacter* infections in intensive care units (ICUs).¹⁹⁻²² AmpC β -lactamase resistance is another particular concern in ICUs. Exposure to β -lactam antibiotics can induce or lead to selection of spontaneous “depressed” mutants that constitutively hyperproduce AmpC.^{9,23,24} AmpC resistance has been demonstrated in many clinically important gram-negative bacteria, including *Acinetobacter* spp., *Citrobacter freundii*, *Enterobacter* spp., *E. coli*, *Morganella morganii*, *P. aeruginosa*, and *Serratia marcescens*.¹⁹ Emergence of AmpC resistance in *Enterobacter* spp. during third-generation cephalosporin therapy may be of particular significance. AmpC β -lactamase inactivates most cephalosporins and aztreonam and is not inhibited by β -lactamase inhibitors.²⁵

Most organisms producing ESBL and AmpC β -lactamase remain susceptible to carbapenems, but carbapenemase-producing gram-negative bacteria have been increasingly reported worldwide.^{26,27} These organisms often display multidrug resistance, with limited treatment options. The most concerning of the carbapenemases are those of *K. pneumoniae* (KPCs). They are mostly plasmid-encoded and hydrolyze all β -lactams, although cephamycins and ceftazidime are weakly hydrolyzed.²⁸ The hydrolytic activity of KPCs is not sufficient to produce resistance against carbapenems but increases the minimum inhibitory concentration (MIC) and potentially the risk of therapy failure. Carbapenemase-producing isolates are generally resistant to all β -lactams as well as aminoglycosides and fluoroquinolones. Colistin and tigecycline typically retain activity against these enzymes.²⁹⁻³¹ Combination therapies with different antibiotic classes³² or newer β -lactamase inhibitors such as avibactam may be alternatives based on in vitro data,³³⁻³⁴ but clinical data supporting such recommendations are lacking.

Spectrum of Activity

β -lactam antibiotics have a wide spectrum of activity against gram-positive and gram-negative aerobic and anaerobic bacteria. However, each individual class of β -lactams has a unique microbiological spectrum. Natural penicillins are seldom used in critical care settings because they lack activity against β -lactamase-producing bacteria. Their utility has been limited to treatment of meningococcal meningitis, streptococcal endocarditis, and streptococcal necrotizing fasciitis. Semi-synthetic penicillins (nafcillin, oxacillin) are usually reserved for infections caused by methicillin-susceptible *S. aureus* (MSSA).

One strategy for achieving β -lactamase stability is combination of β -lactams with β -lactamase inhibitors such as clavulanate, sulbactam, and tazobactam. β -lactamase inhibitors have weak antibacterial

activity but preserve and increase the antibacterial activity of the accompanying β -lactam against β -lactamase producing pathogens. Ampicillin/sulbactam is active against gram-positive bacteria including *Enterococcus* spp., gram-negative cocci, and certain strains of Enterobacteriaceae. Ampicillin/sulbactam does not possess activity against *P. aeruginosa* or ESBL-producing Enterobacteriaceae^{22,35,36} and consequently should not be used as an empiric monotherapy for critically ill patients. Ticarcillin/clavulanate and piperacillin/tazobactam have broader spectrum activity including *P. aeruginosa*, Enterobacteriaceae, and anaerobes such as *B. fragilis*, *Fusobacterium*, and *Prevotella* spp. Piperacillin has better antipseudomonal activity than ticarcillin.^{37,38} However, the susceptibility rates of *P. aeruginosa* to piperacillin/tazobactam in the ICU were reported to be only 70.6% in the United States and 64.7% in Europe,²² necessitating optimization of drug exposure or combination therapy to ensure the efficacy against *P. aeruginosa*. It should be noted that high doses of ampicillin/sulbactam and ticarcillin/clavulanate in combination therapy have demonstrated effectiveness against *A. baumannii* and *Stenotrophomonas maltophilia*, respectively, providing alternative options to treat these pathogens that often exhibit multidrug resistance in the ICU.³⁹⁻⁴¹

Cephalosporins have activity against gram-positive cocci, gram-negative bacilli, and anaerobes, depending on the agent. They are also stable against many β -lactamases. Cephalosporins are broadly divided into five generations. Cefazolin, a first-generation cephalosporin, has activity against MSSA and coagulase-negative staphylococci but may be susceptible to staphylococcal β -lactamase. Cefazolin is also active against most streptococci, but all cephalosporins lack adequate activity against the enterococci. Cefazolin activity against gram-negative bacteria is limited to *E. coli*, *P. mirabilis*, *K. pneumoniae*, *Moraxella catarrhalis*, *Salmonella* spp., and *Shigella* spp. The second-generation cephalosporins are divided into two groups based on their anaerobic activity. Cephamycins such as cefoxitin and cefotetan are active against most gram-negative anaerobic organisms, including *Prevotella* spp., *Fusobacterium* spp., and *B. fragilis*. Cephamycins have less activity against gram-positive bacteria than the first-generation cephalosporins but greater activity against Enterobacteriaceae such as *M. organii*, *P. vulgaris*, *Providencia* spp., and *S. marcescens*. Unfortunately, cefoxitin is a potent inducer of chromosomally mediated β -lactamases.⁴² The second group of second-generation cephalosporins includes cefuroxime. Cefuroxime is stable to most β -lactamases produced by gram-negative bacilli and is more active against methicillin-susceptible staphylococci and streptococci than is cefazolin. With excellent efficacy against *H. influenzae*, cefuroxime is effective against most typical community-acquired respiratory tract pathogens.

Third-generation parenteral cephalosporins include cefotaxime, ceftriaxone, and ceftazidime. These agents can be divided by their antipseudomonal activity, with cefoperazone and ceftazidime having clinically useful potency against *P. aeruginosa*. Cefoperazone possesses a methylthiotetrazole side chain that causes hypoprothrombinemia, limiting its use in the critically ill. Ceftazidime has the greatest potency of the third-generation agents against *S. aureus*. Third-generation cephalosporins have excellent clinical expanded activity against the Enterobacteriaceae and *Streptococcus pneumoniae* but lack activity against enterococci, MRSA, *Listeria monocytogenes*, *S. maltophilia*, and many *Acinetobacter* spp. Third-generation cephalosporins can be hydrolyzed by ESBL-producing Enterobacteriaceae such as *Klebsiella*, *Enterobacter*, and *E. coli*. Cefepime is a fourth-generation cephalosporin with activity similar to that of ceftazidime with better stability to ESBLs.⁴³ The latest marketed product is a combination of ceftazidime and avibactam. Avibactam is a non- β -lactam inhibitor that is able to inhibit Ambler class A, class C, and some class D serine β -lactamases.³⁴ The addition of avibactam improves the activity of ceftazidime against Enterobacteriaceae and *P. aeruginosa*. Avibactam does not improve the activity of ceftazidime against *Acinetobacter* spp., *Burkholderia* spp., or anaerobic gram-negative bacilli.⁴³ Ceftaroline, known as an anti-MRSA cephalosporin, is a fifth-generation cephalosporin with bactericidal activity against MRSA and penicillin-resistant *S. pneumoniae*. It also

has activity against gram-negative bacilli such as *H. influenzae*, *M. catarrhalis*, *E. coli*, and *K. pneumoniae* but lacks activity against ESBL-producing Enterobacteriaceae and *P. aeruginosa*.⁴⁴

The carbapenems are the broadest spectrum β -lactams and are typically reserved for severe nosocomial infections. They are active against most gram-positive bacteria (except MRSA and *Enterococcus faecium*) and gram-negative bacteria (except *S. maltophilia*), as well as anaerobes. Ertapenem is not active against important nonfermenting gram-negative bacilli such as *P. aeruginosa* and *A. baumannii*.⁴⁵ In general, doripenem has been demonstrated to have better activity than imipenem and similar or slightly better activity than meropenem against *P. aeruginosa*.⁴⁶⁻⁴⁷ Aztreonam, a monobactam, has broad aerobic gram-negative activity but lacks efficacy against gram-positive bacteria and anaerobes. Carbapenems are stable against ESBL and AmpC β -lactamase-producing gram-negative bacteria^{48,49} but are susceptible to carbapenemases and metallo- β -lactamases, although these resistance mechanisms are less common. Carbapenems are preferred empiric therapy over β -lactam/ β -lactamase inhibitors or cefepime that are associated with the inoculum effect and increasing resistance rates that can lead to unfavorable clinical outcomes.⁵⁰⁻⁵³ In general, the susceptibility rates of *P. aeruginosa* and *Acinetobacter* isolates to carbapenems in the ICU were 10% to 20% lower than those of non-ICU isolates.²² Only 71.6% and 72.7% of *P. aeruginosa* in the United States and 67% and 66.5% in Europe were susceptible to imipenem and meropenem, respectively. *Acinetobacter* spp. exhibited low susceptibility to imipenem and meropenem in both the United States (43%) and Europe (43%-45%), with increasing prevalence of resistance.²²

Pharmacokinetics and Pharmacodynamics

The pharmacokinetics of β -lactams has not been well investigated in critically ill patients. β -lactams are hydrophilic molecules with a low volume of distribution (Vd), similar to that of extracellular fluid (0.1-0.6 L/kg), with predominant renal clearance.⁵⁴ However, the Vd may be increased in critically ill patients because of sepsis and/or fluid resuscitation, with increased or decreased renal drug clearance.⁵⁵ In healthy volunteers, β -lactam/ β -lactamase inhibitors have a half-life of about 1 hour, and protein binding ranging from 20% to 50%. The primary elimination is by renal excretion, but biliary excretion may be also significant for piperacillin/tazobactam. Most cephalosporins have short half-lives (1-3 hours) and undergo extensive renal elimination. Ceftriaxone, with significant biliary excretion, does not require dosing adjustments in renal dysfunction. The half-life of cefotaxime is not significantly increased in patients with renal failure; however, its active metabolite, desacetylcefotaxime, accumulates significantly and thus requires dosing adjustments. With the exception of ertapenem, all carbapenems exhibit a similar half-life (~1 hour) and small protein binding (2%-20%). Ertapenem is highly protein bound (~95%) and has a 4-hour half-life, allowing once daily administration. Carbapenems are extensively eliminated by the kidney (70%-80%). Reconstituted imipenem and meropenem are stable at room temperature only for 1 to 4 hours, compared with doripenem that displays longer stability (4-12 hours).

β -lactams are time-dependent antibiotics for which the time of free serum concentration above the pathogen MIC ($T > \text{MIC}$) is the pharmacodynamic parameter associated with clinical efficacy.⁵⁶ Typically, bacterial killing occurs when $T > \text{MIC}$ is 50% of the dosing interval for penicillins, 60% to 70% for cephalosporins, and 40% for carbapenems. However, further improved clinical efficacy has been observed when a longer $T > \text{MIC}$ (~100%) is achieved in critically ill patients.^{54,57} In addition, a maximal killing effect and suppressed bacterial resistance have been demonstrated when antibiotic concentrations are maintained at four to five times the MIC, accounting for penetration into the infection sites.^{56,58}

Although therapeutic drug monitoring is not routinely available for β -lactam antibiotics, studies suggest that drug concentrations may be subtherapeutic in critically ill patients given conventional doses.^{59,60} Critically ill patients often have physiologic alterations, including

increased Vd and/or augmented renal clearance. Renal replacement therapy can efficiently eliminate most β -lactam antibiotics. Pathogens with reduced susceptibility and resistance are more common in critically ill patients. Together, these factors commonly observed in critically ill patients warrant aggressive dosing to minimize treatment failure and drug resistance. Prolonged β -lactam infusion—either extended (3–4 hours) or continuous—has been suggested as an alternative dosing strategy to optimize antibiotic exposure, particularly in critically ill patients with resistant gram-negative pathogens including *P. aeruginosa*.^{61–64} The randomized trials report conflicting data regarding the clinical benefits of prolonged β -lactam infusion compared to intermittent dosing.^{62,63,65} A recent meta-analysis found that continuous β -lactam infusion is associated with improved clinical cure and mortality compared with intermittent dosing in severely septic patients without renal replacement therapy. However, a definitive benefit of continuous infusion should be confirmed by a large randomized study.

Adverse Effects

The most common adverse event with penicillin is allergic or hypersensitivity reaction (~10%). The most common presentations of hypersensitivity reactions include maculopapular or urticarial rashes and angioedema, but severe reactions such as anaphylaxis can also occur. A history of penicillin allergy is known to be unreliable in predicting the risk of developing an immediate allergic reaction because hypersensitivity to penicillin can wane with time.^{66,67} Patients with a history of nonanaphylactic penicillin allergy who have a negative penicillin skin test are unlikely to experience hypersensitivity reactions^{67–69} and may be able to receive β -lactam therapy. However, patients who react to the skin test should avoid β -lactams or undergo desensitization.⁷⁰

Cephalosporins are generally well tolerated. Agents with the methylthiotetrazole (MTT) side chain may cause hypoprothrombinemia via inhibition of synthesis and absorption of vitamin K and competitive inhibition of vitamin K-dependent clotting factors. Agents bearing the MTT side chain are cefoperazone, cefotetan, and cefmetazole. Use of these agents may require vitamin K supplementation. The MTT side chain has also been associated with a disulfiram-like reaction.

A higher rate of seizures (1.5%–2%) has been reported when higher imipenem doses (≥ 4 g/day) are administered.^{71,72} Risk factors for imipenem-associated seizures include renal impairment, lower body weight, and history of seizures or other CNS diseases.^{71,73,74} Imipenem is metabolized extensively by renal dehydropeptidase-1 (DHP-1), producing nephrotoxic metabolites. Consequently, imipenem requires coadministration with cilastatin, a DHP-1 inhibitor, to increase the imipenem urine delivery and to prevent nephrotoxicity. Other carbapenems are intrinsically more stable to DHP-1.

Cross-Sensitivity

Approximately 8% of the U.S. population reports a history of penicillin allergy that ranges from mild cutaneous reactions to life-threatening Type 1 IgE-mediated hypersensitivity reactions. Fortunately, the incidence of anaphylaxis to penicillins is low ($\leq 0.02\%$).^{75,76} A history of cephalosporin allergy is only reported in about 1% of the U.S. population.⁷⁷ Cephalosporin-associated toxic epidermal necrolysis, Stevens-Johnson syndrome, severe hepatitis, interstitial nephritis, and hemolytic anemia are extremely rare. Clinically significant immunologic cross-reactivity between β -lactams is much lower than once believed. Cephalosporin allergy in penicillin-allergic patients is attributable to cross-reactive antibodies to side chains similar between cephalosporin and penicillins or amoxicillin. Based on side-chain similarity, first-generation cephalosporins are cross-reactive with penicillins, but cross-reactivity is negligible with second- and third-generation cephalosporins.⁷⁸ Attributable cross-reactivity is very unlikely or absent between penicillins-cephalosporins and carbapenems.⁷⁹ Monobactams

are not cross-reactive with penicillins but are so with ceftazidime because they have identical side chains.⁸⁰

FLUOROQUINOLONES

Mechanism of Action

The fluoroquinolones are another broad-spectrum antibiotic class used in the critical care setting. Ciprofloxacin, levofloxacin, and moxifloxacin are commonly used. Fluoroquinolones impair DNA replication and cause cell death by interfering with normal function of DNA gyrase (gyrA and gyrB) or topoisomerase IV (parC and parE), which condenses DNA into supercoils to allow large amounts of DNA to be packed into the cell.⁸¹ The widespread use of fluoroquinolones has caused an increase in bacterial resistance to these drugs. Resistance derives from mutations in gyrA, gyrB, parC, and parE with or without efflux pump. Multiple forms of resistance can be present simultaneously, further increasing their MIC.⁸²

Spectrum of Activity

Fluoroquinolones have activity against a wide range of both gram-positive and gram-negative organisms. Levofloxacin and moxifloxacin are potent against penicillin-sensitive or -resistant *S. pneumoniae* but inactive against MRSA. Over the years, increasing resistance has reduced the usefulness of fluoroquinolones against gram-negative bacteria. Ciprofloxacin is considered the most potent fluoroquinolone against gram-negative bacteria, with the lowest MIC values, but a higher levofloxacin dose can be used to achieve similar efficacy. Fluoroquinolones are typically stable against ESBL or carbapenemase-producing pathogens. For common resistant ICU pathogens such as *P. aeruginosa*, *A. baumannii*, and *S. maltophilia*, fluoroquinolones are used in combination with β -lactams. The susceptibility of *P. aeruginosa* is approximately 70%, while that of *A. baumannii* is usually less than 50%.²² Although fluoroquinolones are not widely used for anaerobic infections, moxifloxacin does have an FDA indication for intra-abdominal infections.⁸³

Pharmacokinetics and Pharmacodynamics

The oral bioavailability of fluoroquinolones is high (70%–99%) and can be administered orally in patients who can tolerate it. The large Vd following rapid oral absorption suggests adequate tissue concentrations. The long half-lives (4–12 hours) allow once- or twice-daily dosing. Ciprofloxacin and levofloxacin are excreted renally as unmetabolized drug, necessitating dosing adjustments in renal insufficiency. Moxifloxacin, however, is highly metabolized and does not require dose adjustments in either renal or hepatic dysfunction. Fluoroquinolones display concentration-dependent bactericidal effect. The free area under the serum concentration time curve to MIC ratio (f-AUC/MIC) seems to be the best predictor of efficacy. An f-AUC/MIC ratio greater than or equal to 87.5/h best predicts clinical and microbiologic success for gram-negative infections; f-AUC/MIC greater than or equal to 33.7/h maximizes the efficacy against gram-positive infections. Treatment of infection with resistant pathogens such as *P. aeruginosa* and *A. baumannii* requires the maximum fluoroquinolone doses (i.e., intravenous ciprofloxacin 400 mg every 8 hours or levofloxacin 750 mg every 24 hours) in patients with normal renal function.⁸⁴

Adverse Effects

Fluoroquinolones have an acceptable safety profile. Prolongation of the QTc interval, which may predispose susceptible patients to potentially fatal torsades de pointes arrhythmias, has been observed and should be monitored in patients with uncorrected hypokalemia or receiving Class IA or III antiarrhythmics.⁸⁵ *Clostridium difficile*-associated colitis has been associated with fluoroquinolone use but remains

controversial.⁸⁶ Fluoroquinolones may alter the serum glucose concentration (hypo- or hyperglycemia), especially in those patients who have a history of diabetes and are on hypoglycemic agents. Oral absorption of fluoroquinolones is altered by di- or trivalent-cation-containing products (some tube feedings, antacids, multivitamins, ferrous sulfate, sucralfate), and their administration should be separated by at least 2 hours.⁸³

■ AMINOGLYCOSIDES

Aminoglycoside use in the critical care setting is mainly additive or synergistic with β -lactams or fluoroquinolones. Early combination therapy that includes aminoglycosides has shown survival benefit in patients with septic shock.⁸⁷⁻⁸⁹ Aminoglycosides should be given based on once-daily aminoglycoside dosing for a short period of time (5-7 days) to improve effectiveness and reduce nephrotoxicity. Commonly used aminoglycosides are gentamicin, tobramycin, and amikacin.

Mechanism of Action

Aminoglycosides are cations that bind passively to negatively charged portions of the outer membranes of gram-negative bacilli and competitively displace cell wall Mg^{2+} and Ca^{2+} that link lipopolysaccharides. Once inside the cell, aminoglycosides then bind to the 16S rRNA of 30S subunits of ribosomes, causing termination and miscoding of protein synthesis.⁹⁰ In gram-positive bacteria, aminoglycoside uptake is reduced by the thicker outer cell wall membranes; higher MICs are reported.

Spectrum of Activity

Aminoglycosides are active primarily against gram-negative bacteria and staphylococci. Gentamicin is a potent agent against Enterobacteriaceae. Tobramycin has slightly higher activity than gentamicin against *P. aeruginosa* and *Acinetobacter* spp. Amikacin is usually reserved for gram-negative pathogens that are resistant to gentamicin and tobramycin. Aminoglycosides are active against MSSA. For MRSA caused by *Streptococcus* spp. and *Enterococcus* spp., aminoglycosides are used to provide synergistic activity with β -lactam antibiotics.⁹¹ Bacterial resistance to aminoglycosides is caused by modifications of ribosomal binding sites and enzymes, decreased antibiotic uptake, and efflux of antibiotics.⁹²

Pharmacokinetics and Pharmacodynamics

All the aminoglycosides have similar pharmacokinetic properties. Distribution of the drug from the vascular to the extravascular space occurs rapidly, within 15 to 30 minutes post infusion. Aminoglycosides are primarily excreted by glomerular filtration and require dosage adjustments in renal insufficiency. In patients with normal renal function, the half-lives of all aminoglycosides range from 1.5 to 3.5 hours. More than 90% of a parenterally administered dose is recovered in urine unchanged during the first 24 hours. The remainder is slowly recycled into the tubular lumen, where accumulation of the drug causes nephrotoxicity.⁹³ Aminoglycoside concentrations are generally low in infected secretions and tissues.⁹⁴ Inhalation therapy has been used in ventilator-associated pneumonia with resistant organisms.⁹⁵

Pharmacodynamic principles associated with aminoglycosides include concentration-dependent bactericidal activity, postantibiotic effect (PAE), and synergism with other cell-wall-active agents. Rapid bacterial killing against Enterobacteriaceae correlates best with the 24-hour AUC/MIC ratio, while the peak/MIC ratio is better in *P. aeruginosa*. The PAE for *P. aeruginosa* may be as long as 10.2 hours and even longer for Enterobacteriaceae.⁹⁶ Synergy is frequently reported with the combination of an aminoglycoside and a cell wall-active antimicrobial (e.g., β -lactam), even against pathogens with higher MICs. Once-daily dosing employs these pharmacodynamics principles

and administers a larger dose less frequently to produce a rapid bactericidal effect and yet undetectable trough concentrations to reduce drug accumulation.

Adverse Effects

The most common adverse event with aminoglycosides is nephrotoxicity ranging from 5% to 25%.^{93,97} Risk factors for nephrotoxicity include older age, preexisting renal insufficiency, diabetes, concomitant vancomycin use, longer treatment duration (≥ 4 days), and shock/hypotension.⁹⁸ Aminoglycosides may cause ototoxicity that is manifested as auditory (cochlear) and vestibular toxicity. Risk factors include patient age, prolonged therapy of greater than 10 days, renal function, and additive effects of other ototoxic agents (loop diuretics).⁹⁹ The most life-threatening adverse reaction to aminoglycosides, although very rare, is neuromuscular blockade.¹⁰⁰ Blockade results from inhibition of the presynaptic release of acetylcholine and blockage of postsynaptic acetylcholine receptor sites. Risk factors include aminoglycoside given intravenously in patients with renal insufficiency and concomitant administration of a neuromuscular blocking or anesthetic agent.

Dosing and Monitoring

Aminoglycosides are administered in small doses multiple times per day or in large doses less frequently, as in a once-daily dosing, based on a patient's renal function. Once-daily dosing may have similar to better clinical efficacy and delay onset of nephrotoxicity if used in short duration.⁹⁶ Serum concentrations of aminoglycosides are essential for both efficacy and toxicity. For traditional multiple-dose daily regimens, peak and trough concentrations should be checked 1 hour after the start of infusion and right before the next dose, respectively. They should be measured during steady state, which is approximately after the third dose. The frequency of subsequent monitoring should be based on changes in renal function. For lower respiratory tract infections, the target peak concentration should range from 8 to 12 mg/L for gentamicin and tobramycin and 25 to 30 mg/L for amikacin. Trough concentrations should be less than 2 mg/L, although less than 1 mg/L is preferred. For once-daily dosing, the targeted peak concentration should be 20 mg/L or a C_{max}/MIC of 10, and the trough concentration should be undetectable (<0.5 mg/L) for approximately 4 hours at the end of the dosing interval.¹⁰¹ In gram-positive infections such as infective endocarditis, a synergistic effect is achieved with low-dose gentamicin to achieve a peak concentration of 3 μ g/mL and a trough concentration of less than 0.5 μ g/mL.

■ COLISTIN

Polymyxins include polymyxin B and polymyxin E (colistin); colistin has been used more commonly in clinical practice. Colistin use has increased as salvage therapy against multidrug-resistant gram-negative pathogens including *P. aeruginosa*, *A. baumannii*, *K. pneumoniae*, and *Enterobacter* spp.¹⁰² Polymyxins have no appreciable activity against gram-positive bacteria and most anaerobes. Colistin interacts with the lipid A component of lipopolysaccharide (LPS) and displaces the calcium and magnesium bridges that stabilize the LPS. Disruption of the integrity of the outer membrane may lead to increased permeability and improved uptake of colistin, but the ultimate mechanism of their bactericidal activity is not well understood. Currently, resistance to colistin is relatively low, and the mechanism of resistance is not well described.¹⁰³ Modification of the lipid A portion of LPS is associated with resistance in *P. aeruginosa* and *E. coli*, while increased production of capsule polysaccharide is thought to be responsible for *K. pneumoniae* resistance.¹⁰⁴ Further studies are needed to better elucidate the mechanisms of action and resistance.

Colistin is formulated as a prodrug, colistin methanesulfonate (CMS, also known as colistimethate) and available for parenteral or aerosol use. CMS slowly hydrolyzes to the active colistin, with the

*Data compiled from package insert information.

[†]For aminoglycosides dosing, adjusted body weight should be used: $(0.45 \times [\text{total body weight} - \text{ideal body weight}] + \text{ideal body weight})$.

[‡]For colistin, dosing should be based on lower of actual or ideal body weight.

[§]All administration is intravenous; dosing is for serious, life-threatening infections.

q, every; h, hours; CrCl, creatinine clearance; CRRT, continuous renal replacement therapy.

maximum concentration occurring about 7 hours after administration. The half-life of colistin is 14 hours, delaying steady-state attainment to 2 to 3 days. The protein binding of colistin is approximately 60%. About two-thirds of CMS is eliminated renally within 24 hours, but elimination of active colistin is not renal. Colistin achieves adequate concentration in the liver, kidney, heart, and muscle, but is poorly distributed to the bones, cerebrospinal fluid, lung parenchyma, and pleural cavity, requiring nebulization to treat life-threatening respiratory infections.¹⁰⁵ Pharmacodynamic studies suggest that the $f\text{-AUC}/\text{MIC}$ ratio is the optimal parameter to predict the antibacterial effect, indicating that time-averaged exposure to colistin is important.¹⁰⁶⁻¹⁰⁸ A high dose (3 MU of CMS every 8 hours) of colistin does not yield sufficient serum concentrations, especially for resistant gram-negative pathogens showing higher MICs ($\geq 2 \mu\text{g/mL}$).¹⁰⁹ Consequently, a large loading dose and higher maintenance doses may be needed to achieve the target colistin serum concentrations more rapidly.¹¹⁰ However, neph-

rotoxicity is the major dose-limiting adverse effect. Colistin-associated nephrotoxicity is dose-dependent and has been observed in 15% to 25% of patients treated with colistin.^{111,112} Older age, concurrent use of other nephrotoxic agents, hypovolemia/shock, and severe illness may increase the risk of acute kidney injury.

Based on the current understanding of colistin, a CBA loading dose of 5 mg/kg (maximum, 300 mg) is recommended, followed by a maintenance dose starting 24 hours after the loading dose. The maintenance dose can be based on the package insert as presented in Table 116-1. Both the loading and maintenance doses should be based on the lower of the actual or ideal body weight.^{109,113} To improve effectiveness, colistin should be used in combination with other antimicrobial therapy. Synergistic activity was observed with carbapenems and to a lesser extent with fluoroquinolones.¹¹⁴ Ongoing randomized controlled trials comparing colistin-meropenem combinations may shed light on the future direction of colistin use.

KEY POINTS

1. Antibiotics commonly used to treat gram-negative infection in critical care settings include penicillin, cephalosporin, carbapenem, monobactam, fluoroquinolone, and aminoglycosides.
2. β -lactam antibiotics are combined with β -lactamase inhibitors, as in ampicillin/sulbactam, ticarcillin/clavulanate, piperacillin/tazobactam, and ceftazidime/avibactam, to overcome bacterial resistance.
3. Carbapenems and cefepime are more reliable against gram-negative bacteria expressing extended-spectrum β -lactamases.
4. Penicillin allergy is commonly reported, but true anaphylaxis is rare. Cross-reactivity between penicillins and other β -lactams is low, with the highest incidence in first-generation cephalosporins. Cross-reactivity is negligible with other β -lactams.
5. Fluoroquinolones should be combined with β -lactam antibiotics or aminoglycosides until susceptibility is documented.
6. Aminoglycosides should be combined with β -lactam antibiotics or fluoroquinolones for a short duration of 5 to 7 days in septic shock or hypotensive patients.
7. Colistin should be administered in combination with carbapenems for use against multi-drug resistant gram-negative pathogens.

ANNOTATED REFERENCES

- Rea RS, Capitano B, Bies R, et al. Suboptimal aminoglycoside dosing in critically ill patients. *Ther Drug Monit* 2008;30:674–681.
- A retrospective review of 102 MICU patients receiving either gentamicin or tobramycin to determine the probability of achieving $C_{min}/MIC \geq 10$. Only 20% and 40% of patients receiving 7 mg/kg of gentamicin and tobramycin, respectively, achieved this ratio. The low probability was thought to result from the larger distribution volume in ICU patients.
- Paul M, Sibiger I, Grozinsky S, et al. Beta lactam antibiotic monotherapy versus beta lactam-aminoglycoside antibiotic combination therapy for sepsis. *Cochrane Database Syst Rev* 2006;1:CD003344.
- A total of 64 randomized and quasi-randomized trials were included in a meta-analysis to compare any β -lactam monotherapy to any combination of one β -lactam and one aminoglycoside for sepsis. The primary outcome of all-cause mortality did not differ between monotherapy and combination therapy in studies that compared the same β -lactams (RR 1.01; 95% CI, 0.75–1.35) and in studies that compared different β -lactams (RR 0.85; 95% CI, 0.71–1.01). Nephrotoxicity was significantly more frequent with combination therapy (RR 0.30; 95% CI, 0.23–0.39).
- Aarts MW, Hancock JN, Heyland D, et al. Empiric antibiotic therapy for suspected ventilator-associated pneumonia: a systematic review and meta-analysis of randomized trials. *Crit Care Med* 2008;36:108–117.
- Although a total of 41 randomized controlled trials were included in a meta-analysis comparing monotherapy to combination therapy for the empiric treatment of ventilator-associated pneumonia, only two trials evaluated a combination with an aminoglycoside therapy. In these two trials evaluating meropenem versus ceftazidime plus aminoglycoside, no difference in all-cause mortality was reported (RR 0.73; 95% CI, 0.47–1.18), but treatment failure was lower in the meropenem group (RR 0.70; 95% CI, 0.53–0.93).
- Cosgrove SE, Vigliani GA, Campion M, et al. Initial low-dose gentamicin for *Staphylococcus aureus* bacteria and endocarditis is nephrotoxic. *Clin Infect Dis* 2009;48:713–721.
- This secondary analysis of a randomized controlled trial of daptomycin versus vancomycin or anti-staphylococcal penicillin plus gentamicin in patients with *S. aureus* bacteremia and endocarditis was conducted to determine rates of gentamicin-associated nephrotoxicity. All patients receiving standard therapy and patients likely to have left-sided endocarditis in the daptomycin group received the initial 4 days of low-dose gentamicin (1 mg/kg every 8 h, with appropriate dose adjustment). Gentamicin use before enrollment in the randomized study was also reviewed. A clinically significant decrease in creatinine clearance (CrCl) was defined as a decrease in CrCl to <50 mL/min in those with baseline CrCl ≥ 50 mL/min or a decrease ≥ 10 mL/min if the baseline was <50 mL/min. A total of 22% of patients who received versus 8% of patients who did not receive initial low-dose gentamicin experienced a clinically significant decrease in CrCl. Independent predictors of a clinically significant decrease in CrCl were age ≥ 65 years and receipt of initial low-dose gentamicin.
- Oliveira JFP, Silva CA, Barbieri CD, et al. Prevalence and risk factors for aminoglycoside nephrotoxicity in intensive care units. *Antimicrob Agents Chemother* 2009;53:2887–2891.
- A total of 360 patients who received gentamicin or amikacin for at least 4 days were evaluated for risk factors for aminoglycoside-associated nephrotoxicity. Aminoglycoside doses were adjusted based on the calculated glomerular filtration rate (cGFR). Nephrotoxicity was defined as a decrease in the cGFR of 20% or more from the baseline during aminoglycoside use. Logistic regression revealed that a baseline cGFR of <60 mL/min/1.73 m², diabetes, treatment with other nephrotoxic agents or iodinated contrast, and hypotension were independently associated with aminoglycoside-associated nephrotoxicity.
- Buchholtz K, Larsen CT, Hassager C, Bruun NE. Severity of gentamicin's nephrotoxic effect on patients with infective endocarditis: a prospective observational cohort study of 373 patients. *Clin Infect Dis* 2009;48:65–71.
- A database of infective endocarditis patients from two tertiary university hospitals in Copenhagen, Denmark, was evaluated for nephrotoxic effects of gentamicin. Of 373 patients with infective endocarditis, 287 received gentamicin therapy that was adjusted according to serum creatinine and trough drug levels. Kidney function was evaluated using estimated endogenous creatinine clearance (EECC). The mean time on gentamicin therapy was 17 days (range, 1–69). The mean EECC decrease was 8.6%, with a 0.5% decrease noted per day of gentamicin treatment. This decrease in EECC did not correlate to postdischarge mortality. This study did not evaluate the use of other nephrotoxic agents or the gentamicin dose.

Nosocomial infections continue to pose a significant burden on the healthcare system. A recent summary of data reported to the National Healthcare Safety Network (NHSN) showed that gram-positive organisms were leading causes of healthcare-associated infections (HAIs) between 2009 and 2010.¹ Similarly, the EPIC II study in 2007 demonstrated gram-positive organisms were associated with 47% of infections in the ICU.² The causative pathogen can vary depending on the type of ICU as well as the type of HAI. For example, nosocomial bacteremias are caused most often by coagulase-negative staphylococci and occur more commonly in the medical ICU.¹ *Staphylococcus aureus* is the most common pathogen associated with nosocomial pneumonia as well as surgical-site infections.¹ Along with the increase in prevalence of gram-positive cocci in the ICU, staphylococci are becoming multidrug resistant. This chapter addresses gram-positive organisms and resistance issues associated with each of the antimicrobials with activity against these pathogens.

VANCOMYCIN

Vancomycin was discovered in 1956 and marketed in 1958. Early preparations of the drug contained pyrogens and impurities that produced a brownish, muddy appearance that provided vancomycin's nickname, "Mississippi mud." In addition, these pyrogens and impurities caused high fevers, hypotension, severe phlebitis, and possibly nephrotoxicity.³

Mechanisms of Action and Resistance

Vancomycin is a glycopeptide that inhibits synthesis of the cell wall by binding to the D-alanyl-D-alanine terminus of cell wall precursor units and is bactericidal against most gram-positive organisms. In the past decade, the Clinical and Laboratory Standards Institute (CLSI) and the U.S. Food and Drug Administration (FDA) changed the vancomycin breakpoints against *S. aureus* from less than or equal to 4 µg/mL to less than or equal to 2 µg/mL for susceptible strains. Intermediate susceptibility is now 4 to 8 µg/mL, and resistance to vancomycin is greater than or equal to 16 µg/mL.⁴ The European Committee on Antimicrobial Susceptibility Testing (EUCAST) changed their vancomycin interpretations against *S. aureus* to less than or equal to 2 µg/mL as susceptible and greater than 2 µg/mL as resistant. These changes in breakpoints will alter how literature is interpreted with respect to the frequency or prevalence of vancomycin-intermediate or vancomycin-resistant *S. aureus* over the past 30 years.

Five types of resistance to vancomycin have been isolated from enterococci: VanA, VanB, VanC, VanD, and VanE. The VanA phenotype, inducible by vancomycin, confers high-level resistance to both teicoplanin (minimum inhibitory concentrations [MICs]: 16 to 512 µg/mL) and vancomycin (MICs: 64 to greater than 1000 µg/mL), whereas VanB confers low-level resistance primarily to vancomycin. Both have been identified in *Enterococcus faecium* and *Enterococcus faecalis*. VanA, B, D, and E are all transferable to other organisms. In contrast, the VanC phenotypes are endogenous (constitutively produced) and are components of *Enterococcus gallinarum*, *Enterococcus casseliflavus*, and *Enterococcus flavescens* and confer resistance to vancomycin alone.

Vancomycin-intermediate *S. aureus* (VISA), defined using the previous breakpoints of MIC 8 to 16 µg/mL, was first reported from

Japan in 1996; by June 2002, eight cases were confirmed in the United States.⁵ A precursor to VISA, known as heteroresistant vancomycin-intermediate *S. aureus* (hVISA), was described around the same time.⁶ Using the new breakpoints, a surveillance study of 42 U.S. medical centers in 2011 showed an increase in the prevalence of hVISA compared to 2009 (1.2% versus 0.4%), but no VISA was detected.⁷ In June 2002, the first case of vancomycin-resistant *S. aureus* (MIC greater than 32 µg/mL) was identified in Michigan, followed in September 2002 by a second case in Pennsylvania.^{5,8} While the exact mechanism leading to reduced susceptibility in VISA isolates has yet to be determined, many agree that a common element involves thickening of the cell wall. In addition, both strains of vancomycin-resistant *S. aureus* possessed the VanA gene.

Spectrum of Activity

Vancomycin is active primarily against aerobic gram-positive cocci, including *Corynebacterium* and methicillin-resistant *S. aureus* (MRSA). The MIC₉₀ is 1 µg/mL against methicillin-susceptible *S. aureus* (MSSA) and 1 to 2 µg/mL against MRSA.^{7,9} The present incidence of vancomycin-intermediate or vancomycin-resistant *S. aureus* is very low. The activity of vancomycin against enterococci varies greatly with the species. *E. faecium* is the most resistant species of enterococci to vancomycin, with the resistant rates ranging from 30% to 90% depending on the institution. For all enterococci the vancomycin resistance rates are now approximately 35%.¹⁰

Most streptococci are susceptible to vancomycin, although it is considered an agent of last resort against these organisms. Vancomycin has been shown to be inferior to nafcillin or oxacillin for the treatment of MSSA infections. Treatment failures, prolonged treatment, and higher mortality rates were demonstrated when vancomycin was used to treat MSSA infections compared with nafcillin or oxacillin.^{11,12}

Vancomycin is active against anaerobic gram-positive organisms such as *Peptostreptococcus* spp., *Propionibacterium* spp., *Eubacterium* spp., *Bifidobacterium* spp., and most *Clostridium* spp., including *C. difficile*.¹³

Pharmacokinetics/Pharmacodynamics

Vancomycin is administered orally and intravenously (IV). The drug is poorly absorbed after oral administration, and while the majority of the drug is excreted unchanged in feces, inflammation of the gastrointestinal tract may result in increased absorption.¹⁴ Intramuscular injections are extremely painful and should not be used. Vancomycin is approximately 55% bound to plasma proteins. The volume of distribution (*V_d*) corrected for weight ranges is 0.4 to 0.9 L/kg.¹⁵⁻¹⁸ Vancomycin does not penetrate well into aqueous humor or noninflamed meninges; however, penetration ranges from 1% to 37% of serum concentrations in the setting of meningeal inflammation.¹⁹⁻²¹ Penetration is greater than 75% serum concentrations into ascitic, pericardial, and synovial fluids, approximately 50% into pleural fluid, and 30% to 50% into bile.¹⁷ Elimination of vancomycin is 80% to 90% unchanged drug in the urine via glomerular filtration and the remaining via nonrenal elimination (up to 40 mL/min in healthy individuals).²² The half-life of the drug increases with decreased renal function; in patients with creatinine clearances (CrCl) greater than 80 mL/min, the half-life

TABLE 117-1 Dosages for Agents with Primary Activity Against Gram-Positive Bacteria

| DRUG | DOSAGE | ADVERSE EFFECTS | CONSIDERATIONS |
|---------------------------|--|--|--|
| Vancomycin | Oral (PO) and intravenous (IV) administration Dose based on actual body weight (ABW) PO: 125 mg q 6 h IV: 1 g (~15 mg/kg) q 12 h for average-weight adult IV: For morbidly obese adult, dose on ABW ~15 mg/kg/dose | Red man syndrome: erythema, pruritus, flushing of upper torso Thrombophlebitis Ototoxicity: rare Nephrotoxicity: rare Maculopapular or erythematous rashes | Intramuscular injections painful Poorly absorbed orally Half-life of drug increases with decreased renal function Moellering and Matzke methods for dosing guidelines For obese patients and patients on dialysis, consider drug clearance |
| Teicoplanin | PO and IV administration PO: 200 mg BID (<i>Clostridium difficile</i> -associated diarrhea) Moderate infections: 400 mg (6 mg/kg) once followed by maintenance dose 200 mg (3 mg/kg) q 24 h Severe infections: 400-800 mg (6-12 mg/kg) q 12 h for 2-3 doses, followed by 400-800 mg q 24 h | Nephrotoxicity: rare Ototoxicity: rare Hypersensitivity | Special dosage considerations for patients with renal failure, patients on dialysis Compassionate use only in the United States (not FDA approved) |
| Telavancin | IV: 10 mg/kg once daily | Nausea and vomiting Taste perversion Foamy urine Renal impairment | Teratogenic in animal models, further information needed in humans Interferes with common anticoagulation and urine protein dipstick testing |
| Daptomycin | IV: 4 mg/kg q 24 h for average-weight adult for skin and skin-structure infection 6 mg/kg q 24 h for bacteremia/endocarditis | Transient muscle weakness Myalgia | Contraindicated in pneumonia |
| Linezolid | Bioequivalence between PO and IV formulations Moderate infections: 600 mg twice daily Uncomplicated infections: 400 mg twice daily | Reversible myelosuppression Anemia Neutropenia Thrombocytopenia Diarrhea Headache Nausea and vomiting | Oral formulation is bioequivalent to IV formulation Caution with prolonged use and in patients on selective serotonin reuptake inhibitors (SSRIs) |
| Tedizolid | Bioequivalence between PO and IV formulations 200 mg daily for acute bacterial skin and skin structure infections | Nausea, vomiting, diarrhea Headache Dizziness | |
| Quinupristin/dalfopristin | IV: 7.5 mg/kg q 8-12 h infused over 1 h | Arthralgia Myalgia Infusion-related Nausea, vomiting, diarrhea, rash | Last line agent due to significant toxicities |

is 4 to 6 hours. The pharmacodynamic target predicting efficacy has received much attention and is suggested to be an area under the concentration time curve to MIC (AUC/MIC) ratio of 400.²³

Dosage Regimens and Therapeutic Monitoring

Oral Administration

Oral administration of vancomycin is only for treating *C. difficile* colitis. The dose is 125 to 500 mg orally every 6 hours and is not adjusted for renal dysfunction, owing to the poor absorption. Two oral formulations (capsules or liquid) can be used, or the IV solution can be administered orally to treat *C. difficile*. Table 117-1 lists dosing regimens for the antimicrobials discussed in this chapter.

Intravenous Administration in Adults

In nonobese adults with normal renal function, the usual dose of vancomycin is 1 g (~15 mg/kg actual body weight) every 12 hours. This dose results in peak serum concentrations of 25 to 40 µg/mL 1 hour after completion of the infusion and trough serum concentrations of 5 to 15 µg/mL. Several dosing guidelines have been developed to accurately and easily dose vancomycin. The most popular methods include the Moellering¹⁵ and Matzke¹⁶ nomograms. These methods use body weight and CrCl to calculate vancomycin dose. The weaknesses of these nomograms include the small number of patients used to develop and evaluate the nomogram and the fixed volume of distribution assumed for all patients (0.9 L/kg). The variance in volume of distribution (0.4 to 0.9 L/kg) affects the reproducibility of these nomograms when applied to different patient populations. The Cockcroft

and Gault and modified Cockcroft and Gault methods of estimating CrCl are relatively reliable and accurate methods in patients of normal body mass.²⁴

Dosing in the Setting of Obesity

Morbidly obese patients are difficult to dose given the lack of pharmacokinetic studies. Based on recent investigations, actual body weight and CrCl continue to be the best correlate to volume of distribution and vancomycin clearance in this population.²⁵ Additionally, the best prediction of CrCl estimation in the obese patient is via the Salazar-Corcoran method.²⁶ Young obese patients with no comorbid conditions have 2.3 to 2.5 times higher clearance compared with nonobese patients, thus often requiring a more frequent dosing interval to achieve a trough serum concentration of 5 to 15 µg/mL.^{27,28} On the other hand, there is a significant risk in overdosing older obese patients due to the decline in kidney function with age.²⁹

Dosing in Critically Ill Patients

Determination of appropriate dosing of vancomycin in critically ill patients can be challenging due to alterations in the volume of distribution and renal clearance.^{30,31} Pharmacokinetic parameters can vary widely, as was seen in a prospective, multicenter pharmacokinetic point-prevalence study in critically ill patients receiving contemporary dosing.³² Overall, the median (IQR) vancomycin trough was 17 µg/mL (range, 8-23), and 57.1% of patients achieved a trough greater than or equal to 15 µg/mL. Another pharmacokinetic study involving critically ill patients found that those with severe illness (SOFA score greater than or equal to 11), obesity, and unstable renal function had less

predictable pharmacokinetic modeling.³³ These studies highlight the high interpatient variability of vancomycin pharmacokinetics in critically ill patients and the need for individualized treatment regimens.

Dosing in Renal Failure/Dialysis

The removal of vancomycin during intradialytic administration has been studied using three types of cellulose membranes, with mean removal ranging from 13% with cellulose acetate (CA) up to 24% and 26% with CA high performance 210 (CAHP 210) and cellulose triacetate (CT).³⁴⁻³⁶ High-flux synthetic membranes such as polysulfone or polyacrylonitrile remove significantly more vancomycin than do the cellulose membranes, with 30% to 55% and 25% to 40% of vancomycin removed, respectively.^{34,37-41}

Of the most frequently used methods of continuous renal replacement therapy (CRRT), continuous venovenous hemodialysis (CVVHD) and continuous arteriovenous hemodialysis (CAVHD) result in a greater total body clearance of vancomycin than does continuous venovenous hemofiltration (CVVH). The total clearance of vancomycin with CVVHD or CAVHD is 31 to 39 mL/min, and high-volume hemofiltration (HVHF) increases vancomycin clearance to approximately 60 mL/min.⁴²⁻⁴⁶ Therefore, patients receiving CAVHD or CVVHD should receive vancomycin every 36 to 48 hours, and those undergoing HVHF should receive the drug every 12 to 24 hours.⁴⁷ Dosing in patients receiving extended daily dialysis (EDD), a newer modality combining intermittent hemodialysis and CRRT, is much more challenging given the paucity of data that exists in this arena.⁴⁸ Overall, a review of several pharmacokinetic studies in patients receiving various forms of CRRT showed an association between effluent flow rate and vancomycin clearance. However, these findings require additional validation.⁴⁸ Based on the variability in clearances achieved with each of these methods depending on blood flow rate, ultrafiltration rate, and the membranes used, therapeutic drug monitoring remains an effective method of ensuring appropriate vancomycin dosing when CRRT is used.

Dosing in Cardiopulmonary Bypass/Extracorporeal Membrane Oxygenation

Cardiopulmonary bypass (CPB) was found to significantly affect the pharmacokinetic parameters of vancomycin in several small studies over the past 20 years. For example, Ortega et al. observed an immediate decrease in vancomycin serum concentration by 7 µg/mL after initiation of CPB, followed by gradual and steady decreases over the next 30 minutes.⁴⁹ However, a recent prospective, comparative evaluation of vancomycin pharmacokinetics found no difference in maximum plasma concentration (C_{max}), area under the curve (AUC_{0-8}), V_d , and clearance (Cl) between patients undergoing cardiac surgery with and without CPB.⁵⁰

A study of 11 patients receiving extracorporeal membrane oxygenation (ECMO) and continuous infusion vancomycin found a median volume of distribution and total clearance similar to matched controls, reflecting vancomycin's relative stability in ECMO circuits.⁵¹

Therapeutic Drug Monitoring

Routine monitoring of vancomycin serum concentrations has become a highly debated issue over the years. Those who advocate routine monitoring cite the need to ensure therapeutic concentrations as well as minimize toxicities.

Studies have shown that peak concentrations of vancomycin are not associated with toxicities or clinical efficacy. Therefore, monitoring peak serum concentrations has largely fallen out of favor. On the other hand, vancomycin troughs have been heavily studied for their correlation with efficacy and toxicity. A few recent publications found improved outcomes when targeting vancomycin troughs of 15 to 20 µg/mL.^{52,53} In contrast, it has been suggested that vancomycin troughs of this magnitude (greater than or equal to 15 µg/mL) are associated with an increased risk of nephrotoxicity.⁵⁴ Given the lack of consensus, it may be prudent to measure serum trough concentrations until more definitive studies are conducted to address this issue.⁵⁵

Adverse Effects

Common toxicities that have been associated with vancomycin therapy include red man syndrome, thrombophlebitis, ototoxicity, and nephrotoxicity. Evidence establishing a clear relationship between these toxicities and vancomycin peak or trough concentrations or the incidence of these events is limited and contradictory.^{3,56-58}

Red man syndrome comprises erythema, pruritus, and flushing of the upper torso and is often associated with too rapid an infusion of the drug. In general, the infusion rate should not exceed 1 g/h. Less frequently, hypotension and angioedema can occur. It is thought that increased histamine release is the cause of this syndrome, and the effects can be relieved by antihistamines.^{3,57-61}

Ototoxicity rates range from 0% to 9% in patients receiving vancomycin.^{3,57} The definition of ototoxicity ranges from tinnitus to hearing loss. The evidence demonstrating any relationship between ototoxicity and high peak serum concentrations of vancomycin is limited. Reports have been associated with peak serum concentrations anywhere from 37.5 to 152 µg/mL.^{62,63} A trial comparing once-daily to twice-daily dosing of vancomycin demonstrated more frequent ototoxicity in the twice-daily dosed group (15.6% vs. 3.2%), which had a significantly lower peak concentration and similar trough concentration compared to the group receiving daily doses.⁵⁷ This lack of correlation between serum concentrations of vancomycin and ototoxicity suggests that the observed toxicity was caused by either another drug or the combination of another drug with vancomycin. In the majority of cases, ototoxicity symptoms disappear within a month of discontinuing vancomycin.

The issue of nephrotoxicity associated with vancomycin is complicated by several confounding factors. The original formulation was very impure, and the impurities were associated with toxicities, including nephrotoxicity. In addition, many definitions of nephrotoxicity have been used over the years, different patient populations have been studied, and different doses used, making it difficult to compare one study to another. In general, the rate of nephrotoxicity is 5% to 10% when vancomycin is not administered with other nephrotoxic agents, and trough concentrations are less than 10 µg/mL.^{57,64,65} Elting and colleagues identified older age, Acute Physiology and Chronic Health Evaluation (APACHE) score greater than 40, and duration of therapy of greater than 14 days to be the best predictors of a patient developing nephrotoxicity due to vancomycin therapy.³ A number of other studies have found an increased incidence of nephrotoxicity (21%-35%) when vancomycin serum trough concentrations are greater than 10 µg/mL.⁶⁵⁻⁶⁷ In addition, Lodise demonstrated an increased rate of nephrotoxicity (~35%) when the total daily dose is 4 grams or more compared to total doses less than 4 grams (~11%).⁶⁸ Studies have demonstrated higher rates of nephrotoxicity when vancomycin is used in combination with an aminoglycoside compared with either agent alone.^{65,69,70} Goetz performed a meta-analysis of eight studies and found the incidence of nephrotoxicity associated with combination therapy was 13% greater than with vancomycin alone and 4% greater than with an aminoglycoside alone.⁷⁰

Other toxicities associated with vancomycin include maculopapular or erythematous rashes (2%-8%)^{18,71,72} and anecdotal reports of neutropenia and thrombocytopenia.^{71,73}

TEICOPLANIN

Teicoplanin is a glycopeptide antibiotic and is not approved for use in the United States. It is available for use in Europe, some Asian countries, Mexico, New Zealand, and Australia. It has a more favorable adverse-effect profile than vancomycin; however, there is concern over teicoplanin's clinical efficacy in the treatment of severe gram-positive infections.

Mechanisms of Action and Resistance

Teicoplanin, like other glycopeptide antibiotics, inhibits synthesis of the cell wall by binding to the D-alanyl-D-alanine terminus of cell wall

precursor units. Resistance has been reported in both staphylococci and enterococci. The VanA phenotype confers high-level resistance to both teicoplanin (MIC: 16-512 µg/mL) and vancomycin (MIC: 64- >1000 µg/mL). The VanB phenotype has also been identified in both *E. faecium* and *E. faecalis* and usually confers low-level resistance to vancomycin but not to teicoplanin. This resistance may limit the utility of teicoplanin for some vancomycin-resistant enterococcal infections. Several reports of *S. aureus* resistance developing during therapy with teicoplanin have been reported.⁷⁴⁻⁷⁷ The mechanism of the resistance was determined in one patient to be constitutive and non-plasmid-mediated.⁷⁵ Most phenotypes of hVISA and VISA demonstrate cross-resistance to teicoplanin.⁷⁸

Spectrum of Activity

Teicoplanin is only active against gram-positive organisms. Activity against MSSA and MRSA is comparable to that of vancomycin. Coagulase-negative staphylococci have a varied pattern of susceptibility to teicoplanin. *Staphylococcus haemolyticus* is the most resistant species to teicoplanin (30%).⁷² These isolates are 25% more resistant to teicoplanin than to vancomycin. For methicillin-resistant coagulase-negative staphylococci, 39% of isolates have teicoplanin MICs greater than 8 µg/mL compared with 1% with vancomycin.^{72,79} Teicoplanin is similar in activity to vancomycin against enterococci, although its reliability in treating infections with VanB resistance to vancomycin may be limited. Teicoplanin is active against other aerobic and anaerobic gram-positive organisms such as *Corynebacterium* spp., *Clostridium* spp., including *C. difficile* and *C. perfringens*, *Peptostreptococcus* spp., and *Propionibacterium acnes*.

Pharmacokinetics/Pharmacodynamics

Teicoplanin is administered orally and intravenously. The drug is poorly absorbed after oral administration, and approximately 40% of the drug is excreted unchanged in feces. The pharmacokinetic model that best describes the elimination of teicoplanin is triexponential. IV administration of 400 mg (6 mg/kg) should provide a peak serum concentration of 20 to 50 µg/mL attained 1 hour after administration.⁸⁰ The volume of distribution is large, at 0.9 to 1.41 L/kg, and teicoplanin is 90% to 95% protein bound.⁸⁰ Tissue distribution is variable; most notably, penetration is poor into noninflamed meninges and fat but good into myocardium and pericardium.⁸¹ Teicoplanin is primarily eliminated via glomerular filtration, and only 3% is metabolized.⁸⁰ The half-life is approximately 150 hours in patients with normal renal function.⁸⁰ Because of the long half-life, it takes 14 days to reach steady state. In patients with mild to moderate renal dysfunction, the half-life was found to be 157 to 567 hours.^{81,82}

Dosage Regimens and Therapeutic Monitoring

Despite the long half-life in patients with normal renal function, teicoplanin should be administered daily, and the dose is dependent on the severity of infection. For less serious infections involving the urinary tract, skin, soft tissue, and lower respiratory tract, a loading dose of 400 mg (6 mg/kg) × 1 is administered, followed by a maintenance dose of 200 mg (3 mg/kg) every 24 hours. For severe infections such as septicemia, endocarditis, and osteomyelitis, 400 mg of teicoplanin is administered every 12 hours for 3 doses, followed by 400 mg every 24 hours. This dosage reasonably attains levels within the lower therapeutic range of 10 to 20 mg/L. For specific clinical scenarios such as *S. aureus* endocarditis, levels between 20 and 30 mg/L have been recommended. Therefore, higher doses (up to 12 mg/kg) are suggested.^{80,83}

Dosing in Renal Failure/Dialysis

Teicoplanin is not removed by hemodialysis or continuous ambulatory peritoneal dialysis (CAPD).^{84,85} The amount removed by high-flux membranes such as CVVH, CVVHD, and CVVHDF can be

significant.⁸⁶⁻⁸⁸ For renal dysfunction, several dosing regimens exist, with doses even as high as 600 to 1800 mg/day during CVVH.⁸⁷ Even with such high doses, therapeutic drug monitoring is still recommended, given the variability in protein binding and ultrafiltration rates when using CRRT.

Adverse Effects

Nephrotoxicity associated with teicoplanin is much lower than with vancomycin. The incidence from published and unpublished studies found the nephrotoxic rate to be 4%.⁵⁸ Ototoxic rates with teicoplanin are similar to those with vancomycin.⁵⁸ Hypersensitivity reactions are the most common adverse reaction to teicoplanin (2%-15%).⁵⁸

■ TELAVANCIN

Telavancin was approved in the United States in 2009 for the treatment of complicated skin and skin structure infections and in 2013 for hospital-acquired and ventilator-associated pneumonia.

Mechanisms of Action and Resistance

Telavancin is a lipoglycopeptide derivative of vancomycin that has a dual mechanism of action. It binds to the D-alanyl-D-alanine terminus of the cell wall precursors as does vancomycin but additionally binds to bacterial membranes, resulting in depolarization and increased permeability of the membrane.^{89,90} This dual mode of action, in addition to structural differences, allows for enhanced activity against MRSA and some enterococci.⁹¹ The acquired VanA phenotype in enterococci confers resistance to telavancin. However, susceptibility is retained with the VanB phenotype.⁹² Van-mediated resistance in *S. aureus* leads to reduced telavancin activity but not as great as for vancomycin. In vitro studies have shown a low rate of de novo resistance development in both staphylococci and enterococci, even with previous vancomycin exposure, and currently only one case of elevated telavancin MIC has been reported with clinical use.⁹³⁻⁹⁹

Spectrum of Activity

Telavancin is active against MSSA, MRSA, coagulase-negative staphylococci, vancomycin-susceptible enterococci, *Streptococcus pyogenes*, *Streptococcus agalactiae*, and *Streptococcus anginosus*. Breakpoints for susceptibility after changes in testing methods have been updated to less than or equal to 0.06 µg/mL against the *S. anginosus* group, less than or equal to 0.12 µg/mL for other streptococci and staphylococci, and ≤0.25 µg/mL for enterococci (vancomycin susceptible).^{100,101} No interpretations for defining *intermediate* or *resistant* exist at this time. The MIC₉₀ against both methicillin-susceptible and methicillin-resistant *S. aureus* is 0.06 µg/mL, and despite higher MICs, telavancin does have activity against vancomycin-intermediate and vancomycin-resistant strains (MIC ranges of 0.03-0.25 µg/mL, 0.06-0.5 µg/mL, and 0.25-8 µg/mL against hVISA, VISA, and VRSA, respectively).¹⁰²⁻¹⁰⁷ Against *Enterococcus* spp., telavancin is slightly less potent, and greater activity is seen against vancomycin-resistant strains with VanB over those with VanA.^{92,102-107} Telavancin is active against most anaerobic gram-positive organisms including *C. difficile* and *C. perfringens*.¹⁰⁸

Pharmacokinetics/Pharmacodynamics

Telavancin is administered IV and demonstrates linear pharmacokinetics over doses of 7.5 to 15 mg/kg. In healthy subjects, doses of 7.5 and 15 mg/kg at steady state resulted in mean C_{max} serum concentrations of 88 and 186 µg/mL and trough concentrations of 6 and 16 µg/mL, respectively.¹⁰⁹ Approximately 70% of telavancin is renally eliminated, and the half-life was dose dependent and ranged from 6 to 7.5 hours.¹⁰⁹ Telavancin is 90% protein bound to albumin and has a volume of distribution of approximately 0.14 L/kg.¹⁰⁰ Telavancin

penetrates lung epithelial lining fluid and alveolar macrophages well, and concentrations exceeded 0.5 µg/mL during the entire dosing interval.¹¹⁰ Penetration into blister fluid is approximately 40% of serum concentrations but only 1% to 2% into inflamed meninges.^{111,112}

Telavancin exhibits rapid concentration-dependent killing. The pharmacodynamic parameter identified in animal models as the best predictor of efficacy is the AUC/MIC ratio, with a target of 219 resulting in optimal killing.^{113,114}

Dosage Regimens and Therapeutic Monitoring

For both complicated skin and skin-structure infections and hospital-acquired/ventilator-associated pneumonia, telavancin is dosed 10 mg/kg IV every 24 hours when CrCl is over 50 mL/min.

Dosing in Renal Failure/Dialysis

Because of the high urinary elimination of telavancin, dosage reductions are required when the patient's CrCl falls below 50 mL/min. If CrCl is 30 to 50 mL/min, the dose of telavancin is 7.5 mg/kg every 24 hours; when less than 30 mL/min, the dose is further reduced to 10 mg/kg every 48 hours.^{100,114} Hemodialysis does not have a significant impact on telavancin removal.¹¹⁵ In vitro studies evaluated the effect of CRRT on telavancin elimination and found high ultrafiltrate or dialysate rates can remove a significant amount of telavancin, which could require supplemental dosing.¹¹⁶

Dosing in the Setting of Obesity

A linear relationship is seen between body weight and clearance, thus supporting the milligram per kilogram dosing strategy; however, further investigation is warranted given the potential overestimation of CrCl using total body weight.^{117,118}

Adverse Effects

Telavancin is a pregnancy category C drug with little information available in pregnant women. In three animal species, telavancin was found to have fetal effects including decreased birth weight and increased digit and limb malformations. A serum pregnancy test should be performed in women of childbearing age before starting telavancin. A pregnancy exposure registry is available should there be a need to use telavancin in a pregnant woman.¹⁰⁰

The most common adverse effects associated with telavancin are nausea, vomiting, diarrhea, taste disturbance, foamy urine, and renal impairment.^{100,119-122} An increase in mortality was seen in patients with moderate to severe renal dysfunction treated with telavancin for HABP/VABP.¹²² Telavancin interferes with urine protein qualitative dipstick tests, and several anticoagulation tests including PT, APTT, INR, ACT, and factor X activity assays.¹⁰⁰ For this reason, concomitant use with unfractionated heparin is contraindicated.^{100,123a} When measuring anticoagulation, these tests should be performed as close as possible prior to a patient's next dose or alternative monitoring methods considered.¹⁰⁰

DAPTOMYCIN

Daptomycin is a lipopeptide that was first discovered in the 1980s and was approved in 2003 by the FDA for complicated skin and skin structure infections and in 2006 for *S. aureus* bloodstream infections, including right-sided endocarditis.

Mechanisms of Action and Resistance

Daptomycin has a unique mechanism of action and has been found to inhibit lipoteichoic acid synthesis by binding to the membrane in the presence of calcium.^{124,125} To date, there have been several case series and case reports describing daptomycin resistance in patients with *S. aureus*.¹²⁶ The mechanism appears to be multifactorial, with cell wall changes being largely implicated. Development of resistance

in enterococcus has been observed as well.¹²⁷ However, in contrast to *S. aureus*, genetic pathways appear to be the key alterations explaining this phenomenon. Clinically, the development of resistance has led to treatment failures and the need for salvage therapy.

Spectrum of Activity

Daptomycin's antibacterial activity encompasses most gram-positive bacteria, including vancomycin-resistant isolates and penicillin-resistant pneumococci. The MICs of daptomycin are 8- to 16-fold lower in the presence of calcium. Therefore, all in vitro testing must be supplemented with physiologic concentrations of calcium.¹²⁸ The breakpoint for susceptibility is less than or equal to 1 µg/mL for staphylococci and β-hemolytic streptococci. Given the rare number of isolates not susceptible to daptomycin, a resistant breakpoint has yet to be determined. The MIC90 against MSSA, MRSA, *Staphylococcus epidermidis*, and *Staphylococcus saprophyticus* are all 0.5 µg/mL or less.^{128,129} In a recent surveillance study, 53 *S. aureus* and 41 coagulase-negative staphylococci were nonsusceptible to daptomycin.¹³⁰ Daptomycin initially appeared active against vancomycin-intermediate and vancomycin-resistant strains of *S. aureus*. However, a recent analysis of 33 VISA isolates found 70% resistance to daptomycin.¹³¹⁻¹³³ Interestingly, 100% of VRSA isolates were susceptible, possibly due to the difference in resistance mechanisms. The breakpoint for susceptibility against enterococci is less than or equal to 4 µg/mL, and again no resistant breakpoint has been established. Against *E. faecalis* and *E. faecium*, including vancomycin-resistant strains, the MIC90 is 2 µg/mL or less.^{128,129} Daptomycin resistance is higher among *E. faecium* than *E. faecalis*.¹³⁰ The MIC90 is 0.25 µg/mL against *S. pneumoniae* and β-hemolytic streptococci, and resistance has not been reported with these organisms.^{128,129}

Pharmacokinetics/Pharmacodynamics

Healthy volunteers who received 6 mg/kg of daptomycin given as either a 30- or 2-minute infusion achieved bioequivalent pharmacokinetic results. The C_{max} was about 94 and 88 µg/mL for the 2- and 30-minute infusions, respectively.¹³⁴ Daptomycin demonstrates linear kinetics at dosing from 4 to 12 mg/kg, and the half-life is 7 to 9 hours in patients with normal renal function.¹³⁵ The drug is 90% to 95% protein bound and is primarily eliminated by the renal route. In patients with CrCl less than 30 mL/min, end-stage renal disease/hemodialysis/peritoneal dialysis, a 4 mg/kg dose should provide peak serum concentrations around 25 to 30 µg/mL and half-life of about 30 hours.¹³⁵

Daptomycin is rapidly bactericidal and exhibits concentration-dependent killing against gram-positive organisms including enterococci.^{124,125} Daptomycin also exhibits a postantibiotic effect that allows for once-daily dosing.¹³⁶

Dosage Regimens and Therapeutic Monitoring

For complicated skin and skin-structure infections (cSSSIs), dosing of daptomycin is 4 mg/kg every 24 hours. Dosing for bacteremia or right-sided endocarditis is 6 mg/kg every 24 hours.¹³⁵ Limited clinical evidence suggests consideration of higher doses (8-12 mg/kg) in specific scenarios such as MRSA bacteremia after vancomycin failure and deep-seated enterococcal infections.

Dosing in Renal Failure/Dialysis

In patients with CrCl less than 30 mL/min or undergoing hemodialysis or chronic peritoneal dialysis, the dose should be reduced to 4 mg/kg every 48 hours and 6 mg/kg every 48 hours for bacteremia or endocarditis.¹³⁵ In patients undergoing continuous renal replacement therapy (CRRT), the amount of daptomycin removed is dependent upon the type of filter and the flow rates.¹³⁷ Dosing recommendations for patients undergoing CRRT are 4 to 6 mg/kg every 48 hours, and there is some speculation that doses may need to be increased to 8 to 10 mg/kg every 48 hours or 4 to 6 mg/kg every 24 hours.¹³⁸⁻¹⁴³ Similarly,

a dose of 6 mg/kg every 24 hours has been proposed for patients receiving extended daily dialysis (EDD).¹⁴⁴

Dosing in the Setting of Obesity

Two single-dose studies using 4 mg/kg total body weight have been performed in moderately and morbidly obese patients. The C_{\max} was increased 25% to 60% compared to normal-weight patients, and the area under the curve (AUC) increased 30% to 60% in the obese patients.^{145,146} Based on this, recommendations have been to base daptomycin dosage on total body weight. However, a subset analysis of patients receiving daptomycin 6 mg/kg for bacteremia and endocarditis found that patients over 111 kg were more at risk for creatinine phosphokinase (CPK) elevations.¹⁴⁷ Despite this, there is currently insufficient evidence to routinely use other weight measurements, such as ideal body weight or adjusted body weight, when determining daptomycin dosage.

Dosing in Burn Patients

One study evaluated single-dose pharmacokinetics (4 mg/kg) in burn patients and found the C_{\max} was 44% lower, with 47% lower AUC and an increase in volume of distribution and clearance.¹⁴⁸ The authors suggest a dose of 10 to 12 mg/kg in burn patients should provide the same drug exposure as 6 mg/kg in healthy volunteers.

Adverse Effects

Creatine phosphokinase (CPK) concentrations increased in 2.8% of patients treated with daptomycin in the cSSSI studies, and 9.2% in the bacteremia/endocarditis trial.^{125,135} Elevations in CPK can occur 2 to 3 days before clinical signs or symptoms of myopathy present.¹³⁶

LINEZOLID

Linezolid was approved in 2000 by the FDA for several indications involving susceptible gram-positive organisms, including skin and skin structure infections, community-acquired and nosocomial pneumonia, and vancomycin-resistant *Enterococcus faecium* infections (including those with concomitant bacteremia).

Mechanisms of Action and Resistance

Linezolid is an oxazolidinone antibiotic, a new class of synthetic agents. Linezolid binds to the 50S ribosome and inhibits the binding of mRNA, thereby preventing protein synthesis.¹⁴⁹ Clinical isolates of *S. aureus*, *E. faecium*, and *E. faecalis* resistant to linezolid have been identified but rates are low (<1.0%) and have remained relatively stable over the past decade.¹⁵⁰ The most common mechanism of resistance is alteration of the 23S rRNA.¹⁵¹ A second mechanism of resistance involves acquisition of the natural resistance gene, *cfr*, and has been increasing in linezolid nonsusceptible isolates in recent years.^{150,152,153} This finding is worrisome because the *cfr* gene confers resistance to other antimicrobial classes, including chloramphenicol and clindamycin. Additionally, this gene may become transmissible, and the first human acquisition of a clinical isolate with this gene on a transferable plasmid was described in 2012.¹⁵⁴ These resistance issues, although rare, do raise concern and emphasize the importance of appropriate use of linezolid.

Spectrum of Activity

The breakpoint for susceptibility to linezolid is less than or equal to 4 µg/mL for staphylococci and less than or equal to 2 µg/mL for enterococci and streptococci. It is active against both methicillin-susceptible and methicillin-resistant staphylococci. The MIC₉₀ against *S. aureus* and coagulase-negative staphylococci is 1 and 0.5 µg/mL, respectively.¹⁵⁰ Against vancomycin-intermediate and vancomycin-resistant *S. aureus*, the drug is active with MIC₉₀ of 4 and 2 µg/mL, respectively.^{123b,123c} Linezolid is equally active against both vancomycin-susceptible and

vancomycin-resistant enterococci, with an MIC₉₀ of 1 µg/mL.¹⁵⁶⁻¹⁵⁹ Against both penicillin-susceptible and penicillin-resistant *S. pneumoniae*, the MIC₉₀ is 1 µg/mL.^{150,156,157} Linezolid is also active against a variety of other organisms, including *Pasteurella multocida*, *Peptostreptococcus* spp., *Fusobacterium* spp., and *Prevotella* spp.

Pharmacokinetics/Pharmacodynamics

Linezolid is available in both oral and IV formulations. Oral absorption is over 90%, making the oral formulation bioequivalent to the IV formulation. The peak serum concentration and half-life at steady state after 600 mg twice daily is 14 to 18 µg/mL and 5 to 6 hours.¹⁶⁰⁻¹⁶² Linezolid is approximately 30% protein bound and penetrates quickly into bone, fat, and muscle, achieving 50% to 60% of serum concentrations in bone and 90% to 95% in muscle.¹⁶³ Cerebrospinal penetration has been documented in patients with meningitis at a fluid/plasma ratio around 1.¹⁶⁴⁻¹⁶⁷ Elimination of linezolid is 30% renal and 70% metabolized, with essentially no linezolid eliminated in feces as unchanged drug.¹⁶² Linezolid is not an inducer of the cytochrome P450 enzyme system.

Linezolid is bacteriostatic against staphylococci and enterococci and is bactericidal against streptococci. It appears that the pharmacodynamic parameter that best models the killing activity is the AUC/MIC ratio.¹⁶⁸ The AUC/MIC ratio required to produce a bacteriostatic effect varied from 22 to 97 (mean 48) for pneumococci and 39 to 167 (mean 83) for staphylococci. A dosage regimen of 600 mg twice daily achieves these values for organisms with MICs as high as 4 µg/mL.

Dosage Regimens and Therapeutic Monitoring

The usual dose of linezolid is 600 mg twice daily, and for uncomplicated skin and skin structure infections, the dose is 400 mg twice daily.

Dosing in Critically Ill Patients

A handful of studies have evaluated the pharmacokinetics of linezolid in critically ill patients.¹⁶⁹⁻¹⁷² Most recently, Zoller and colleagues found significant variability in linezolid serum concentrations in those receiving standard dosing, with 63% of their critically ill patients achieving insufficient levels based on an AUC₂₄/MIC₉₀ target of 100.¹⁷³ To improve drug delivery, a few studies utilizing continuous infusion have been performed and did demonstrate higher rates of target attainment.^{169,172} Thus, continuous infusion, in conjunction with therapeutic drug monitoring, may provide an option for optimizing the pharmacodynamic parameters, but further studies are needed to assess the efficacy and safety of these strategies.

Dosing in Renal Failure/Dialysis

Hemodialysis removes approximately 30% of linezolid during a 3- to 4-hour session, and limited data exist on peritoneal dialysis removal. However, no dosage adjustment is needed in patients with renal dysfunction or end-stage renal disease. During different modalities of CRRT, linezolid removal is variable and has the potential to lead to subtherapeutic levels; however, further studies are warranted to determine the true impact that RRT has on linezolid pharmacokinetics.¹⁷⁴

Dosing in Burn Patients

In a small study of severe burn patients, the volume of distribution and renal clearance were similar to healthy controls; however, total clearance was higher, likely the result of increased nonrenal clearance in those with thermal injuries (323 + 191 vs. 80.4 + 27.5 mL/min, $P = 0.063$).¹⁷⁵

Adverse Effects

Reversible myelosuppression is the most significant adverse effect associated with linezolid therapy. Anemia, neutropenia, and thrombocytopenia have all been reported, and the incidence increases with

durations of therapy exceeding 14 days.^{176,177} The decrease in hemoglobin when linezolid therapy is greater than 2 weeks is 18% compared with 13% for comparator agents and linezolid therapy less than 2 weeks' duration.¹⁷⁶ The thrombocytopenia rate is 8%, with the longer duration of therapy compared with 5% to 6% in all durations of therapy compared with 3% with comparator agents. Rates of neutropenia also increase to about 10% with extended durations of therapy. Complete blood cell counts should be monitored weekly, especially in patients in whom the duration of therapy is likely to exceed 2 weeks.

Linezolid is a reversible, nonselective inhibitor of monoamine oxidase; therefore, the potential for interaction with adrenergic and serotonergic agents exists. Several case reports of serotonin syndrome (fever, agitation, tremors, and mental status changes) secondary to an interaction between linezolid and selective serotonin reuptake inhibitors (SSRIs) have been identified.¹⁷⁸

Serious reactions, including optic or peripheral neuropathy, have been increasingly reported and are generally seen after longer durations of linezolid therapy.¹⁷⁸ Optic neuropathy tends to be reversible upon discontinuation of linezolid, but peripheral neuropathy tends to be permanent.¹⁷⁸ The mechanism underlying this neuropathy is thought to involve the inhibition of mitochondrial protein synthesis.^{178,179} Lactic acidosis, another potentially fatal effect, is also thought to be caused by prolonged therapy and mitochondrial disruption.¹⁸⁰

Other adverse reactions to linezolid include diarrhea (8%), headache (7%), nausea and vomiting (6% and 4%), dizziness, rash, fever, constipation (2%), and abnormal liver function tests (1%).

TEDIZOLID

FDA-approved in 2014, tedizolid is currently indicated only for the treatment of acute bacterial skin and skin-structure infections (ABSSSIs). This new definition of skin and skin-structure infection is based on the 2013 FDA Guidance for Industry, which seeks to assist clinical development of drugs for this specific indication.

Mechanisms of Action and Resistance

Tedizolid phosphate, the prodrug of the active moiety tedizolid, is a second-generation oxazolidinone. It acts via a mechanism similar to linezolid in preventing protein synthesis by binding to the 50S ribosome.¹⁸¹ Owing to the incorporation of a D-ring substituent and a hydroxymethyl group, however, tedizolid exhibits 4- to 8-fold greater potency against staphylococcal, streptococcal, and enterococcal isolates.^{182,183} These structural changes are also responsible for tedizolid's ability to maintain activity against some oxazolidinone-resistant organisms. Specifically, tedizolid was shown to have MIC values between 0.5 and 1 mg/L against MRSA possessing the *cfr* gene, compared to a 4- to 8-fold elevation in MIC seen with linezolid.^{184,185} Cross-resistance to tedizolid can occur, however, and is likely mediated by a combination of alterations in 23S rRNA or ribosomal proteins L3 and L4.^{185,186} Overall, the spontaneous development of resistance to tedizolid is low.¹⁸⁷

Spectrum of Activity

The breakpoint for susceptibility to tedizolid is less than or equal to 0.25 µg/mL for streptococci in the *Streptococcus anginosus* group and less than or equal to 0.5 µg/mL for other streptococci, enterococci, and staphylococci (including both methicillin-resistant and methicillin-susceptible isolates). The MIC₉₀ against *S. aureus*, and coagulase-negative staphylococci is 0.5 µg/mL.¹⁸⁸ Against hVISA, VISA and daptomycin-nonsusceptible (DNS) *S. aureus*, tedizolid demonstrates activity with an MIC₉₀ value of 0.5 µg/mL against all pathogens.¹⁸⁹ Higher MICs were seen when tedizolid was tested against linezolid-resistant isolates of *S. aureus* (range 1 to 8 µg/mL), albeit much lower than the MICs to linezolid (range, 8-64 µg/mL).¹⁹⁰ Tedizolid is equally active against both vancomycin-susceptible and vancomycin-resistant enterococci with an MIC₉₀ of 0.5 µg/mL, and against

linezolid-resistant enterococci, the MIC ranged from 1 to 4 µg/mL.^{188,190} Tedizolid exhibited similar potency against penicillin-susceptible and penicillin-resistant *S. pneumoniae* with an MIC₉₀ of 0.25 µg/mL.¹⁸⁸

Pharmacokinetics/Pharmacodynamics

Tedizolid is available in both oral and IV formulations as tedizolid phosphate, a prodrug that is rapidly converted by serum phosphatases to the active tedizolid compound. Oral absorption is approximately 90%.^{191,192} The mean maximum plasma concentration ranged from 1.8 to 2.4 µg/mL at 2 to 3 hours after oral administration, with a mean half-life of approximately 11 hours.¹⁹¹ Tedizolid is 90% protein bound and is widely distributed into soft tissues ($V_d = 108$ L), including significant accumulation in epithelial lining fluid (ELF).^{193,194} Elimination of tedizolid is 20% renal and 80% via the liver as an inactive sulfate conjugate.^{195,196} Tedizolid has low affinity for cytochrome P450 enzymes, and weak, reversible inhibition of MAO was seen in vitro.^{181,197} Clinically, however, this did not translate into a significant increase in head twitch response in a 5-hydroxytryptophan murine head twitch model, in contrast to linezolid, which did.

Tedizolid is bacteriostatic and early models suggest that the free AUC to MIC ratio ($fAUC/MIC$) is the pharmacodynamic parameter most reflective of tedizolid killing of staphylococci.^{198,199} The AUC/MIC ratio required to produce bacteriostasis and a 1 log₁₀ reduction in CFU in neutropenic models was 20 and 35, respectively. A 25-fold increase in activity is seen in the presence of granulocytes; therefore, a 200-mg once-daily regimen effectively achieves target attainment against *S. aureus* with MIC less than or equal to 0.5 µg/mL.²⁰⁰⁻²⁰²

Dosage Regimens and Therapeutic Monitoring

The usual dose of tedizolid is 200 mg once daily for the treatment of acute bacterial skin and skin-structure infections (ABSSSIs). This FDA approval is based on one phase II and two phase III clinical trials that evaluated the efficacy and safety of tedizolid.²⁰²⁻²⁰⁴ At this time, there have been no completed studies exclusively in critically ill patients. However, a phase III study is currently ongoing comparing tedizolid versus linezolid for the treatment of hospital-acquired bacterial pneumonia (HABP) and ventilated nosocomial pneumonia (VNP).²⁰⁵

Study of patients with extensive renal (estimated glomerular filtration rate <30 mL/min/1.73 m²) and hepatic impairment (Child Pugh 7-9 and Child Pugh 10-15) suggest that no adjustment of tedizolid dosage is required for these populations, as their pharmacokinetics were not significantly altered versus healthy controls.¹⁹⁶ Additionally, hemodialysis does not influence the pharmacokinetics of tedizolid, nor does it significantly remove the drug.¹⁹⁶

Adverse Effects

The potential for myelosuppression, similar to that observed with linezolid, exists with tedizolid and was studied in healthy adults receiving 200 to 400 mg of tedizolid daily for 21 days.²⁰⁶ Significant hematologic changes were not observed at any point in those receiving 200 mg daily; however, changes were seen between days 8 and 21 in those receiving 400 mg daily. In phase II studies of shorter durations (5 to 7 days), hematologic parameters remained stable.²⁰⁷ A pooled analysis of two phase III trials in patients receiving tedizolid for ABSSSI found a lower incidence of thrombocytopenia (platelet count <150,000 cells/mm³) compared to those receiving linezolid (3.2% vs. 5.6%, day 7-9 visit).²⁰⁸ These results suggest that tedizolid may have less harmful hematologic effects than linezolid.

Monoamine oxidase inhibition by tedizolid was also evaluated in human and animal studies. No significant rise in blood pressure was seen with pseudoephedrine or tyramine administration in either rats or humans, nor was there a significant increase in serotonergic response in mice.^{197,209,210} Despite these findings, the true impact of this interaction remains to be seen as more widespread use of tedizolid takes place.

The potential for neurotoxicity was evaluated in rats receiving tedizolid for up to 9 months. No evidence of neuropathy was found, even at exposures sixfold higher than those used in humans.²¹¹ Similarly, no reports of optic or peripheral neuropathy were seen after a 10-day course of tedizolid in healthy adults.²¹²

Overall, the most common adverse reactions seen with tedizolid include nausea (8%), headache (6%), diarrhea (4%), vomiting (3%), and dizziness (2%).¹⁸¹

■ QUINUPRISTIN/DALFOPRISTIN

Mechanisms of Action and Resistance

Quinupristin/dalfopristin is a streptogramin antibiotic and is a mix of two different streptogramin components from groups A and B. The individual components are bacteriostatic, but the combination is often bactericidal. Each component binds to different sites on the 50S subunit of the ribosome, inhibiting translation of mRNA at the elongation step.²¹³ The resulting complex of drug and ribosome inhibits protein synthesis.

Streptogramins share similar sites of action with macrolide and lincomycin antibiotics. As a result, mechanisms of resistance are also shared. The most common type of resistance to streptogramins involves the erythromycin resistance methylase (*erm*) genes, termed *MLS_B*.²¹⁴ These genes decrease the binding of antibiotics such as streptogramins group B, erythromycin, and clindamycin by dimethylating a residue on the 23S ribosome. Group A streptogramins are not affected, and the combination often retains its synergistic activity.²¹⁴ Enzymatic modification of both components is another mechanism of resistance to the drug.^{215,216} The third mechanism involves efflux pumps: one that pumps out both macrolides and streptogramins and one specific for streptogramins.^{215,217,218}

Spectrum of Activity

Quinupristin/dalfopristin is active against a wide variety of gram-positive organisms as well as many anaerobes and oral flora organisms. An MIC of 2 µg/mL or less indicates susceptibility. The MIC₉₀ of most MSSA, MRSA, and coagulase-negative staphylococci is 1 to 2 µg/mL.^{129,219} Against vancomycin-intermediate and vancomycin-resistant *S. aureus*, the drug is active with MICs of 0.25 to 1 µg/mL.^{132,220} Both vancomycin-susceptible and vancomycin-resistant *E. faecium* are susceptible to quinupristin/dalfopristin (MIC₉₀: 1–4 µg/mL); however, *E. faecalis* is resistant to quinupristin/dalfopristin (MIC₉₀: 4–32 µg/mL).^{219–221} Against a variety of streptococcal organisms, including penicillin-resistant pneumococci, the MIC₉₀ ranges from 0.5 to 2 µg/

mL. Quinupristin/dalfopristin is also active against a variety of other organisms including *Chlamydia* spp., *Mycoplasma pneumoniae*, *Legionella* spp., *Peptostreptococcus* spp., *Fusobacterium* spp., *Prevotella* spp., *Actinomyces* spp., and *Clostridium* spp.

Pharmacokinetics/Pharmacodynamics

Quinupristin/dalfopristin infusions should be administered over 1 hour, and the drug is incompatible with saline. In healthy volunteers and in patients undergoing CAPD, the mean peak serum concentration of quinupristin was 2.6 and 2.9 µg/mL, respectively, and for dalfopristin it was 7.1 and 8.5 µg/mL, respectively, following a single 7.5-mg/kg dose.²²² Quinupristin/dalfopristin is hepatically metabolized to several active metabolites, and both the parent components and the metabolites are primarily eliminated via bile into feces.²²³ Urinary excretion of quinupristin/dalfopristin and metabolites is 15% to 19%. The mean half-life ranges from 1.2 to 1.5 hours. The drug is 90% protein bound.²²⁴

Quinupristin/dalfopristin is bactericidal against staphylococci and streptococci, but it is bacteriostatic against *E. faecium*. The pharmacodynamic parameters that best predict efficacy have not been well characterized.

Dosage Regimens and Therapeutic Monitoring

The normal dose of quinupristin/dalfopristin is 7.5 mg/kg every 8 to 12 hours and infused over 1 hour. Dosage reduction is likely required in patients with severe liver dysfunction, although specific recommendations are not available.

Dosing in Renal Failure/Dialysis

Neither hemodialysis nor peritoneal dialysis removes any appreciable amount of quinupristin/dalfopristin.^{222,225} Penetration into the peritoneal cavity is negligible in CAPD patients. No dosage adjustment is needed in patients with renal insufficiency or on dialysis.

Adverse Effects

Myalgias (6%–7%) and arthralgias (9%–9.5%) are the most severe adverse effects and are often the reason for discontinuation of the drug.^{226,227} Elevations in direct and conjugated bilirubin and γ-glutamyl transferase are common. Infusion-related adverse effects occur in 30% to 45% of patients with peripheral lines used for the infusion.²²⁶ The reactions include pain, burning, inflammation, and thrombophlebitis. Other toxicities include nausea, diarrhea, vomiting, and rash.

KEY POINTS

Vancomycin

1. Vancomycin is bactericidal against most gram-positive organisms. Vancomycin resistance of the VanA phenotype confers high-level resistance to both teicoplanin and vancomycin. Resistance is relatively common within *Enterococcus*. In 2002, this resistance gene was passed to two different *Staphylococcus aureus* isolates and for the first time conferred high-level resistance to vancomycin within the *Staphylococcus* genus.
2. The pharmacodynamic effect of vancomycin is time-dependent killing or time above the minimum inhibitory concentration (MIC). There is no documented correlation between serum peak concentrations and clinical outcomes, whereas vancomycin troughs have been heavily studied.

3. Ototoxicity rates range from 0% to 9%, and these numbers have not changed from initial studies conducted in the 1960s through studies conducted in the 2000s. There is no correlation between serum concentration and ototoxicity. The rate of nephrotoxicity when vancomycin is not administered with other nephrotoxic agents or when trough concentrations are less than 10 µg/mL is 5% to 10%. Trough concentrations of more than 10 µg/mL result in nephrotoxicity rates of 20% to 35%.

Teicoplanin

1. Teicoplanin is a glycopeptide antibiotic with similar activity to vancomycin, approved in several countries outside the United States. There is concern over teicoplanin's clinical efficacy in

KEY POINTS—cont'd

severe gram-positive infections compared to vancomycin, despite a more favorable side-effect profile.

Telavancin

1. Telavancin was approved by the FDA in September 2009 for treating complicated skin and skin-structure infections and 2013 for hospital-acquired and ventilator-associated pneumonia. The drug is categorized as pregnancy category C; however, teratogenicity in animals has been observed (digit and limb malformation and decreased birth weight).
2. Telavancin interferes with anticoagulation tests including INR, PT, APTT, and ACT, and therefore use with unfractionated heparin is contraindicated. These tests should be performed when telavancin concentrations are lowest in the blood.

Daptomycin

1. Approved for bacteremia, right-sided endocarditis, and complicated skin and skin-structure infections. It is contraindicated for lung infections, as surfactant breaks down the drug. Creatine phosphokinase concentrations increase 2 to 3 days before clinical manifestation of symptoms and are derived 100% from the MM isoenzyme.

Linezolid

1. Oral absorption is over 90%, making the oral drug bioequivalent to the intravenous formulation. Linezolid is bacteriostatic against staphylococci and enterococci.

2. Reversible myelosuppression is the most significant adverse effect associated with linezolid therapy. Anemia, neutropenia, and thrombocytopenia have all been reported, and the incidence of these complications increases with duration of therapy exceeding 14 days.
3. Linezolid is a reversible nonselective inhibitor of monoamine oxidase; therefore, the potential for interaction with adrenergic and serotonergic agents exists. Case reports of serotonin syndrome secondary to an interaction between linezolid and selective serotonin reuptake inhibitors have been reported.

Tedizolid

1. Tedizolid is a second-generation oxazolidinone approved for treatment of acute bacterial skin and skin structure infections. Tedizolid is thought to have a lower potential for myelosuppression, neurotoxicity, and monoamine oxidase inhibition compared with its predecessor linezolid; however, the impact of these factors remains to be seen with further clinical use.

Quinupristin/Dalfopristin

1. This drug is active against vancomycin-resistant *Enterococcus faecium*, methicillin-resistant *S. aureus*, vancomycin-intermediate *S. aureus*, and vancomycin-resistant *S. aureus*. It has no activity against *Enterococcus faecalis*. Myalgias (6%-7%) and arthralgias (9%-9.5%) are the most severe adverse effects and are reasons for discontinuation of the drug.

Therapeutic monitoring of vancomycin in adult patients: a consensus review of the American Society of Health-System Pharmacists, the Infectious Diseases Society of America, and the Society of Infectious Diseases Pharmacists. *Am J Health Syst Pharm* 2009;66:82-98.
Vancomycin guidelines developed provide the evidence or lack of evidence supporting the dosing, monitoring efficacy, and toxicity of vancomycin therapy. This is the first guideline for the use of vancomycin.
- Chakraborty A, Roy S, Loeffler J, Chaves RL. Comparison of the pharmacokinetics, safety and tolerability of daptomycin in healthy adult volunteers following intravenous administration by 30 min infusion or 2 min injection. *J Antimicrob Chemother* 2009;64:151-158.

A small pharmacokinetic study performed in two different healthy adult populations was conducted to assess the pharmacokinetics and safety of rapid bolus administration of daptomycin. The 2-minute infusion was bioequivalent to the standard 30-minute infusion with regard to C_{max} and AUC. The 2-minute infusion was well tolerated.

Small study in healthy volunteers evaluating the penetration of telavancin into ELF and alveolar macrophages. Over the entire dosing interval, concentrations in the ELF and macrophages was greater than 0.5 µg/mL. Telavancin is stable in the presence of pulmonary surfactant.

Infections caused by anaerobic bacteria are common and may be serious and life-threatening. Anaerobes are predominant components of the bacterial flora of the normal human skin and mucous membranes¹ and are a common cause of endogenous bacterial infections. Because of their fastidious nature, they are difficult to isolate and are often overlooked. Their isolation requires appropriate methods of collection, transportation, and cultivation.²⁻⁵ Treatment of anaerobic bacterial infections is complicated by the relatively slow growth of these organisms, frequent polymicrobial nature, and growing resistance to antimicrobials.

Antimicrobial resistance among anaerobes has increased in the past three decades, and their susceptibility has become less predictable.⁶⁻¹³ The most commonly isolated antibiotic-resistant anaerobes are those that belong to the *Bacteroides fragilis* group.¹⁴ This increase makes the choice of appropriate empiric therapy more difficult. Resistance patterns have been monitored through national and local surveys, but susceptibility testing of anaerobic bacteria at individual hospitals is rarely done.¹⁰ This chapter describes the antimicrobials effective against anaerobic bacteria and the resistance of these organisms against them.

ANTIMICROBIAL AGENTS EFFECTIVE AGAINST ANAEROBIC BACTERIA

Table 118-1 illustrates the antimicrobials effective against anaerobic bacteria and their efficacy against both aerobic and anaerobic bacteria. Table 118-2 illustrates the resistance of bacteria from the *B. fragilis* group and other anaerobes to antimicrobials.

Beta-Lactam Antibiotics

Penicillin G is the classical drug of choice when the infecting strains are susceptible. Most *Clostridium* strains (except some *Clostridium ramosum*, *C. clostridioforme*, and *C. innocuum*) and *Peptostreptococcus* spp. remain susceptible to penicillin. Most *B. fragilis* groups are resistant to penicillin. Other strains that may show resistance are growing numbers of anaerobic gram-negative bacilli (AGNB), such as pigmented *Prevotella* and *Porphyromonas* spp., *Prevotella oralis*, *P. bivia*, *B. disiens*, strains of *Clostridia*, *Fusobacterium* spp. (*Fusobacterium varium* and *Fusobacterium mortiferum*), and microaerophilic streptococci. Some of these strains show minimum inhibitory concentration (MIC) of 8 to 32 units/mL of penicillin G. In these instances, administration of very high dosages of penicillin G (for non-beta-lactamase producers) may eradicate the infection.

Ampicillin, **amoxicillin**, and penicillin are generally equal in activity to penicillin G, but the semisynthetic penicillins are less active. **Methicillin**, **nafcillin**, and the isoxazolyl penicillins (**oxacillin**, **cloxacillin**, and **dicloxacillin**) are ineffective against the *B. fragilis* group, have unpredictable activity, and are frequently inferior to penicillin G against anaerobes.¹⁵

Penicillin and ampicillin/amoxicillin are of limited utility due to the production of beta-lactamases by many oral and most intra-abdominal anaerobes. Clavulanate, sulbactam, and tazobactam irreversibly inhibit beta-lactamase enzymes produced by beta-lactamase-producing *Fusobacterium* spp. and AGNB.¹⁵⁻¹⁷ When used in combination with a beta-lactam antibiotic (e.g., **ampicillin-sulbactam**, **amoxicillin-**

clavulanate, and **piperacillin-tazobactam**), they are effective in treating anaerobic infections caused by beta-lactamase-producing bacteria (BLPB).

Beta-lactam/beta-lactamase inhibitor combinations (BL-BLICs) are appropriate choices for mixed aerobic-anaerobic infections. They have maintained good activity against most anaerobes. While 89% of *B. fragilis* are susceptible to ampicillin-sulbactam, 98% are susceptible to piperacillin-tazobactam⁸ compared to 86% and 92%, respectively, for *B. thetaiotaomicron* isolates. Recently, the Infectious Diseases Society of America (IDSA) removed ampicillin-sulbactam from the recommended list of drugs for intra-abdominal infections due to increased *Escherichia coli* resistance.¹⁸ Amoxicillin-clavulanate remains the agent of choice for human and animal bite wound infections,¹⁹ especially when anaerobes may be involved. Piperacillin-tazobactam is also a frequently and appropriately prescribed agent for serious intra-abdominal infections. It has also maintained good activity against most anaerobes.⁸

The semisynthetic penicillins, the carboxy-penicillins (**carbenicillin** and **ticarcillin**), and ureidopenicillins (**piperacillin**, **azlocillin**, and **mezlocillin**), generally are administered in large quantities to achieve high serum concentration. These drugs are effective against Enterobacteriaceae and have good activity against most anaerobes at these concentrations. However, up to 30% of the bacteria in the *B. fragilis* group is resistant.²⁰

Many anaerobes possess cephalosporinases, and therefore cephalosporins have limited utility.²¹ The activity of **cephalosporins** against the beta-lactamase-producing AGNB varies. The antimicrobial spectrum of the first-generation cephalosporins against anaerobes is similar to penicillin G, although on a weight basis, they are less active. Most strains of the *B. fragilis* group and many *Prevotella*, *Porphyromonas*, and *Fusobacterium* spp. are resistant to these agents.²² Cephalosporinases have little or no hydrolytic activity against the second-generation **cefoxitin** (a cephamycin), which is the most effective cephalosporin against the *B. fragilis* group. However, susceptibility may vary by geographic location and is generally directly related to its clinical use. Cefoxitin is relatively inactive against most species of *Clostridium*, including *C. difficile*, with the exception of *C. perfringens*.²²⁻²⁴

Cefoxitin is often used for surgical prophylaxis at most body sites that involve mucous membranes. With the exception of moxalactam, the third-generation cephalosporins are not as active against *B. fragilis*.

Currently, approximately 85% of *B. fragilis* isolates are susceptible to cefoxitin, but the other *B. fragilis* group species are more resistant.⁸ Cefotetan is less effective than cefoxitin against *B. fragilis* and other members of the *B. fragilis* group. Recently, the IDSA removed cefotetan from the recommended list of drugs against intra-abdominal infections due to poor *B. fragilis* group activity and resultant clinical failures.²⁵⁻²⁷

The carbapenems (imipenem, meropenem, doripenem, and ertapenem) have excellent activity against anaerobes.²⁸ **Imipenem**, a thienamycin, is a beta-lactam antibiotic that is effective against a wide variety of aerobic and anaerobic gram-positive and gram-negative organisms, including *B. fragilis*.^{29,30} It is also effective against most Enterobacteriaceae, with about 5% to 15% of *Pseudomonas* spp. resistance.³¹ To overcome the problem of renal metabolism of imipenem, it is combined at a 1:1 ratio with an inhibitor of the renal dipeptidase, ciliastatin.

TABLE 118-1 Antimicrobial Agents Effective Against Mixed Infections

| ANTIMICROBIAL AGENT | ANAEROBIC BACTERIA | | AEROBIC BACTERIA | |
|--|-------------------------------|-----------------|---------------------|--------------------|

Amp-Sulb, ampicillin/sulbactam; Amx-Clav, amoxicillin/clavulanate; Pip-Tazo, piperacillin/tazobactam; Fox, cefoxitin; Ert, ertapenem; Imi, imipenem; Mero, meropenem; Dori, doripenem; Clinda, clindamycin; Moxi, moxifloxacin; Tige, tigecycline.

Metronidazole is not included since >99% of gram-negative strains are susceptible.

This agent is an effective single agent for the treatment of mixed aerobic-anaerobic infections.

Meropenem antibacterial activity is similar to imipenem. However, it is less active against staphylococci and enterococci and provides better coverage of aerobic and facultative gram-negative bacteria.³² Meropenem has been effective in abdominal infections, meningitis in children and adults, community-acquired and nosocomial pneumonia, and neutropenic fever.³³

Ertapenem, a newer 1-beta-methyl carbapenem, is stable to dehydropeptidase and has a broad antibacterial spectrum for aerobic and anaerobic bacteria, including *C. perfringens*, *Fusobacterium* spp., *Peptostreptococcus* spp., and AGNB.³⁴ Compared to other available carbapenems, ertapenem has a long half-life of 4.5 h and is given as a single daily dose. It is not active against *Pseudomonas aeruginosa*, *Enterococcus* spp., and *Acinetobacter* spp.

Doripenem, a synthetic 1-beta-methyl carbapenem, possesses a similar antimicrobial spectrum to meropenem and imipenem.³⁰ It has significant in vitro activity against aerobic and anaerobic bacteria including the *B. fragilis* group. In vitro, resistant *P. aeruginosa* mutants appear to be harder to select with doripenem than with other carbapenems.

Carbapenems are generally employed in more serious anaerobic infections such as intra-abdominal and skin and soft tissue infections.²⁵⁻²⁷ Recent reports have noted the development of some carbapenem resistance among anaerobes,¹² ranging from 1.1% to 2.5% in a multicenter U.S. survey but higher in a small number of isolates from Taiwan.³⁵

Resistance to β -Lactam Antibiotics

Anaerobes manifest three major resistance mechanisms to β -lactam antibiotics: inactivating enzymes, mainly beta-lactamases (BLAs), which include penicillinases and cephalosporinases, low-affinity penicillin binding proteins (PBPs), and decreased permeability through alterations in the porin channel.³⁶ The production of BLAs is the most common mechanism of resistance to β -lactam antibiotics in anaerobes, especially among the *B. fragilis* group and *Prevotella* spp.³⁷ Typically, the cephalosporinases belong to the 2e class type and can be inhibited by three beta-lactamase inhibitors, clavulanic acid, sulbactam, and tazobactam. Each individual cephalosporin may have either a class or specific inhibitor enzyme that is able to inactivate it.

Carbapenemases are active against the carbapenems as well as all β -lactam antibiotics. Carbapenem resistance occurs in <1% of U.S. isolates, and up to 3% of *Bacteroides* strains harbor one of the genes that is expressed at a very low level.

With a few exceptions among some *Clostridium* spp., strains of *Clostridium*, *Porphyromonas*, and *Fusobacterium* have also been found to express resistance by one or more of the BLAs. BLA producing *Fusobacterium* and *Clostridium* spp. express enzymes that are generally inhibited by clavulanic acid.³⁸ Resistance to β -lactam antibiotics through changes in the OMP/porin channels, decreased PBP affinity, and efflux pumps³⁹ is less well studied. The bacteria in the *B. fragilis* group are generally resistant to penicillins (average 90%), piperacillin (25%), cefoxitin (25%), cefotetan (30%-85%), and third-generation cephalosporins.^{40,41} The combinations of BL/BLICs inhibitors and carbapenems have maintained their excellent antibacterial activity. The combination of ampicillin-sulbactam, amoxicillin clavulanate, ticarcillin-clavulanate, and piperacillin-tazobactam is generally very active against members of the *B. fragilis* group.⁴⁰ However, species-to-species variation in susceptibility occurs.⁴² *B. fragilis* group resistance rates for piperacillin-tazobactam is generally <1%.⁴⁰ However, resistance of *Parabacteroides distasonis* to ampicillin-sulbactam has risen to 20% in 2002-2004 but continued to be low for the other *B. fragilis* group species.

The carbapenems (imipenem, meropenem, doripenem, and ertapenem), are very effective against all members of the *B. fragilis* group, and resistance is rare at <0.1%.^{39,42,43} Geometric mean MICs for imipenem and meropenem for *P. distasonis*, *B. thetaiotaomicron*, and *B. ovatus* have been reported to be one-fold dilution lower than those for ertapenem⁴⁰ in 2004.

β -lactams are generally effective against non-*B. fragilis* group species, and resistance to them is generally low except that more than half of *Prevotella* spp. may also produce BLAs. A multicenter survey²⁹ found penicillin resistance for *Fusobacterium* spp., *Porphyromonas* spp., and *Peptostreptococcus* spp. at 9%, 21%, and 6%, respectively. No resistance was found to cefoxitin, cefotetan, β -lactam/BLA inhibitor combinations, and carbapenems in that survey, with the exception of *Peptostreptococcus* spp. and *Porphyromonas* spp. (4% and 5% resistance to ampicillin-sulbactam, respectively). Beta-lactamases were identified in several *Prevotella* and *Porphyromonas* spp. recovered from pediatric intra-abdominal infections.

Chloramphenicol

Chloramphenicol, a bacteriostatic agent, is active against most anaerobic bacteria but is rarely used in the United States.^{3,22} Resistance is rare. Although several failures to eradicate anaerobic infections with chloramphenicol have been reported,⁴⁴ this agent has been used for over 65 years for treatment of anaerobic infections. In the past, it was the drug of choice for the treatment of serious anaerobic infections including the central nervous system (CNS). However, the drug has potential significant toxicity. The risk of fatal aplastic anemia with chloramphenicol is estimated to be approximately one per 25,000-40,000 patients treated. This serious complication is unrelated to the reversible, dosage-dependent leukopenia. Other side effects include the production of the potentially fatal "gray baby syndrome" when given to neonates, hemolytic anemia in patients with G6PD deficiency, and optic neuritis in those who take the drug for a prolonged time.⁴⁵

Chloramphenicol has a unique property of lipid solubility to permit penetration across lipid barriers. Levels in the cerebrospinal fluid, with or without meningitis, usually are one-third to three-fourths the serum concentrations. Levels in brain tissue may be substantially higher than serum levels.⁴⁶

Macrolides: Erythromycin, Azithromycin, Clarithromycin

The macrolides, which possess low human or animal toxicity, have moderate to good in vitro activity against anaerobic bacteria other than

the *B. fragilis* group and *Fusobacterium*.²² Macrolides are active against pigmented *Prevotella* and *Porphyromonas* and microaerophilic streptococci, gram-positive non-spore-forming anaerobic bacilli, and certain clostridia. They are less effective against *Fusobacterium* and *Peptostreptococcus* spp.⁴⁷ They show relatively good activity against *C. perfringens* and poor or inconsistent activity against AGNB.

Clarithromycin is the most active of the macrolides against gram-positive oral cavity anaerobes, including *Actinomyces* spp., *Propionibacterium* spp., *Lactobacillus* spp., and *Bifidobacterium dentium*. Azithromycin is slightly less active than erythromycin against these species.⁴⁷ Azithromycin is the most active macrolide against AGNB: *Fusobacterium* spp., *Bacteroides* spp., *Wolinella* spp., and *Actinobacillus actinomycetemcomitans*, including those resistant to erythromycin. Clarithromycin showed similar activity to erythromycin against most AGNB.⁴⁸

Erythromycin resistance during therapy can occur.^{49,50} Erythromycin is effective in the treatment of mild to moderately severe anaerobic soft tissue and pleuropulmonary infections when combined with adequate débridement or drainage of infected tissue. Phlebitis is reported to develop in one-third of the patients receiving intravenous erythromycin, but the oral preparation is well tolerated.

Clindamycin

Clindamycin has a broad range of activity against anaerobes. It is used to treat dental infections, especially in patients allergic to penicillin and to treat aspiration pneumonia. Clindamycin hydrochloride is rapidly absorbed from the gastrointestinal tract.⁵¹⁻⁵³ It rapidly penetrates into body tissues and fluids, including saliva, sputum, respiratory tissue, pleural fluid, soft tissues, prostate, semen, bones, and joints,⁵⁴ as well as into fetal blood and tissues. Clindamycin does not efficiently cross the blood-brain barrier or eye and should not be administered in CNS infections.

The side effect of most concern is *C. difficile*-associated colitis.^{55,56} Colitis has also been associated with a number of other antimicrobials, such as ampicillin, cephalosporins, and quinolones, and occasionally also in the absence of previous antimicrobial therapy.

Because *B. fragilis* resistance to clindamycin is increasing, it is no longer recommended as an empiric therapy for intra-abdominal infections.^{12,40,43,57} An 8-year study revealed that 19.3% of 2721 *B. fragilis* group isolates, 29.6% of *P. distasonis*, 33.4% of *B. ovatus*, 33.3% of *B. thetaiotaomicron*, and 35.6% of *Bacteroides vulgatus* strains were clindamycin resistant. This is a significant increase compared to only 3% clindamycin resistance in 1987.⁴¹

Resistance has also increased, for many non-*Bacteroides* anaerobes. Up to 10% resistance was noted in *Prevotella* spp., *Fusobacterium* spp., *Porphyromonas* spp., and *Peptostreptococcus* spp., with higher rates for some *Clostridium* spp. (especially *C. difficile*).²⁹ *Propionibacterium acnes* isolates have also become more resistant to clindamycin, and this has been associated with prior therapy for acne.⁵⁸

Clindamycin has lost some of its activity against anaerobic gram-positive cocci (*Finegoldia magna*, 30% resistant, *Peptoniphilus* spp., etc.) and *Prevotella* spp. (*P. bivia*, 70% resistant; *P. oralis* and *P. melaninogenica*, both 40% resistant), although its activity against *Fusobacterium* and *Porphyromonas* spp. remains good.

Among the other resistant anaerobes are various species of *Clostridium*, especially *C. difficile*. Approximately 20% of *C. ramosum* are resistant to clindamycin, as are a smaller number of *C. perfringens*.

Metronidazole and Tinidazole

Metronidazole and tinidazole have excellent in vitro activity against most obligate anaerobic bacteria, such as the *B. fragilis* group, other species of *Bacteroides*, *Fusobacterium*, and *Clostridium*.³⁴ Only six strains of the *B. fragilis* group were ever reported to be clinically resistant and associated with therapeutic failure.²

Resistance of anaerobic gram-positive cocci is rare, and nonsporulating bacilli are common. Microaerophilic streptococci, *P. acnes*, and

Actinomyces spp. are almost uniformly resistant.⁵⁹ Aerobic and facultative anaerobes are usually highly resistant. Because of its lack of activity against aerobic bacteria, an antimicrobial effective against these organisms (e.g., a cephalosporin, a fluoroquinolone) needs to be added when treating a polymicrobial infection.

Adverse reactions to metronidazole are rare and include CNS toxicity, ataxia, vertigo, headaches, convulsions, and peripheral neuropathy. Peripheral neuropathy is associated with prolonged metronidazole use. Gastrointestinal side effects are common and include nausea, vomiting, metallic taste, anorexia, and diarrhea. Other adverse reactions include reversible neutropenia, phlebitis at intravenous infusion sites, and drug fever.

Some studies in mice^{60,61} have shown possible mutagenic activity associated with administration of large doses of metronidazole. Other experiments⁶¹ in rats and hamsters did not show any pathology. In addition, no evidence of mutagenicity was found in humans.⁶²

Metronidazole is effective in the treatment of anaerobic infections, including those of the CNS.^{63,64} Valid data on the safety of metronidazole in pregnancy is still needed. The nonteratogenicity of metronidazole is difficult to prove, but the existing data indicate no major risks.⁶⁵

Resistance to metronidazole among the *B. fragilis* group is rare.^{33,66} Half of the resistant *B. fragilis* group isolates carry one of nine known *nim* genes [*nim* A-I] on either a chromosome or a mobilizable plasmid. This gene encodes a nitroimidazole reductase that converts 4- or 5-nitroimidazole to 4- or 5-aminoimidazole, preventing the formation of toxic nitroso residues necessary for the agents' activity. Resistance among gram-positive organisms that are not strict anaerobes is frequent, especially for *P. acnes* and *Actinomyces* spp.

Tetracyclines

Tetracycline is of limited use because of the development of resistance to it by most anaerobes. Resistance to *P. acnes* has been related to previous use.⁵⁸ Only about 45% of all *B. fragilis* strains presently are susceptible to this drug.²² The tetracycline analogues, doxycycline and minocycline, are more active than the parent compound. Because of significant resistance to these drugs, they are useful only when susceptibility tests can be performed or in less severe infections in which a therapeutic trial is feasible. The use of tetracycline is not recommended before 8 years of age because of its adverse effect on teeth.

Tygecycline is a glycylcycline, a direct analog of minocycline with a 9-glyclamide moiety. It has activity against both aerobic gram-negative and gram-positive bacteria, anaerobes,^{67,68} and certain drug-resistant pathogens.⁶⁹ It is active against the *Streptococcus anginosus* group (which includes *S. anginosus*, *S. intermedius*, and *S. constellatus*), *B. fragilis*, *B. thetaiotaomicron*, *B. uniformis*, *B. vulgatus*, *C. perfringens*, *C. difficile*, and *Parvimonas micra* (*Peptostreptococcus micros*).⁶⁷ Resistance of tygecycline for members of the *B. fragilis* group varied from 3.3% to 7.2%.^{12,40}

Fluoroquinolones

Quinolones with low activity against anaerobes include ciprofloxacin, ofloxacin, levofloxacin, fleroxacin, pefloxacin, enoxacin, and lomefloxacin. Compounds with intermediate antianaerobic activity include sparflaxacin and grepafloxacin.⁷⁰ **Trovaflaxacin**, **gatifloxacin**, and **moxifloxacin** yield low MICs against most groups of anaerobes.⁷¹ The use of trovaflaxacin has been limited because of hepatotoxicity. Quinolones with the greatest in vitro activity against anaerobes include clinafloxacin and sitafloxacin.⁷²

Moxifloxacin has been studied as monotherapy in intra-abdominal infections in adults^{25,57} and has shown activity against intra-abdominal anaerobic isolates.^{73,74} However, the increasing fluoroquinolone resistance in both the *E. coli* and *B. fragilis* groups has reduced its use in intra-abdominal infections.^{9,12,57,74}

The use of quinolones is restricted in growing children because of their possible adverse effects on cartilage. The major concerns with the use of fluoroquinolones to treat anaerobic infections have been the increasing resistance in the *B. fragilis* group as well as anaerobic gram-positive cocci and the impact of these antibiotics on the growing incidence of *C. difficile*-associated disease.⁷²

Bacteroides spp. resistance to fluoroquinolone has been attributed to either an alteration in efflux of the antibiotic or a mutation in the quinolone resistance determining region (QRDR) of the gyrase A gene (*gyrA*) from either single or multiple mutations.⁷⁵ High-level resistance can be caused by both mechanisms.

Other Agents

Bacitracin was active in vitro against pigmented *Prevotella* and *Porphyromonas* spp. but is inactive against *B. fragilis* and *Fusobacterium nucleatum*.²² Vancomycin and daptomycin are effective against all gram-positive anaerobes but are inactive against AGNB.⁷⁶ Quinupristin/dalfopristin shows antibacterial activity against some anaerobic organisms that were tested, including *C. perfringens*, *Lactobacillus* spp., and *Peptostreptococcus* spp.⁷⁷ Linezolid is active against *Fusobacterium nucleatum*, and other *Fusobacterium* spp., and *Porphyromonas* spp., *Prevotella* spp., *Peptostreptococcus* spp.⁴⁸ Little clinical experience has, however, been gained in the treatment of anaerobic infections using these agents.

GENERAL CONSIDERATION OF ANTIMICROBIAL SELECTION

Because anaerobic infection is often polymicrobial, antimicrobials effective against both aerobic and anaerobic components of the infection should be administered. When such therapy is not given, the infection may persist, and serious complications may occur.^{2,3,78} A number of factors should be considered when choosing appropriate antimicrobial agents: they should be effective against all target organism(s), induce little or no resistance, achieve sufficient levels in the infected site, have minimal toxicity, and have maximum stability and longevity.

When selecting antimicrobials for the therapy of mixed infections, their antibacterial spectrum and their availability in oral or parenteral form should be considered (see Table 118-1). Some antimicrobials have a limited range of activity. For example metronidazole is only active against anaerobes and therefore cannot be administered as a single agent for the therapy of mixed infections. Other antimicrobials, such as carbapenems, tigecycline, and BL-BLICs, possess a broader spectrum of activity against aerobic and anaerobic bacteria.

Selecting antimicrobials is simplified when a reliable culture result is available. However, this may be particularly difficult in anaerobic infections because of the difficulties in obtaining appropriate specimens. For this reason, many patients are treated empirically on the basis of suspected, rather than established, pathogens. Fortunately, the types of anaerobes involved in many anaerobic infections and their antimicrobial susceptibility patterns tend to be predictable.^{2,3} However, some anaerobes have become resistant to antimicrobials, and many can develop resistance during therapy.^{39,79}

Aside from susceptibility patterns, other factors influencing the choice of antimicrobial therapy include the pharmacologic characteristics of the various drugs, their toxicity, their effect on the normal flora, and bactericidal activity.^{2,3} Although identification of the infecting organisms and their antimicrobial susceptibility may be needed for selection of optimal therapy, the clinical setting and Gram stain preparation of the specimen may indicate the types of anaerobes present in the infection as well as the nature of the infectious process.

Typically, antimicrobial therapy for anaerobic infections should be given for prolonged periods because of their tendency to relapse. This may range from 3 weeks to 3 months, depending on the site and severity of the infection.

KEY POINTS

1. Because anaerobic infection is often polymicrobial, antimicrobials effective against both aerobic and anaerobic components of the infection should be administered. When such therapy is not given, the infection may persist, and serious complications may occur.
2. Anaerobes are often involved in mixed infections, which present unique situations for antimicrobial use. The interactions between the different bacteria and the various antibiotics can be difficult to distinguish and/or predict.
3. Selecting antimicrobials is simplified when a reliable culture result is available. However, this may be particularly difficult in anaerobic infections because of the difficulties in obtaining appropriate specimens.
4. Susceptibility patterns of anaerobes have been changing over the years, and susceptibility to metronidazole cannot be assumed. Although susceptibility testing of anaerobes is difficult, clinicians must realize the importance of performing and analyzing the susceptibility tests.
5. Several β -lactam antibiotics, fluoroquinolones, clindamycin, and tigecycline possess activity against anaerobic organisms. However, resistance is a concern with all of these classes of antibiotics. A few investigational agents have the potential for use in anaerobic infections, but clinical data are needed.

ANNOTATED REFERENCES

Aldridge KE, Ashcraft D, O'Brien M, et al. Bacteremia due to *Bacteroides fragilis* group: distribution of species, beta-lactamase production, and antimicrobial susceptibility patterns. *Antimicrob Agents Chemother* 2003;47:148–153.

This paper presents susceptibility data on 542 blood isolates of the B. fragilis group tested over a 12-year period. Metronidazole, β -lactam/ β -lactamase combinations, and carbapenems were consistently the most active agents. These data show the importance of susceptibility testing of the B. fragilis group and serve as a guide in the choice of empiric antimicrobial therapy.

Lamp KC, Freeman CD, Klutman NE, et al. Pharmacokinetics and pharmacodynamics of the nitroimidazole antimicrobials. *Clin Pharmacokinet* 1999;36:353–373.

This review presents a comprehensive overview of the pharmacokinetics, pharmacodynamics, and use of metronidazole and nitroimidazole antimicrobials.

Pelaez T, Alcalá L, Alonso R, et al. Reassessment of *Clostridium difficile* susceptibility to metronidazole and vancomycin. *Antimicrob Agents Chemother* 2002;46:1647–1650.

C. difficile is generally assumed to be sensitive to metronidazole and vancomycin. However, this manuscript shows that some isolates are either resistant (6.3% for metronidazole) or have intermediate resistance (3.1% to vancomycin) to these agents.

Snydman DR, Jacobus NV, McDermott LA, et al. Lessons learned from the anaerobe survey: historical perspective and review of the most recent data (2005–2007). *Clin Infect Dis* 2010;50:S26–S33.

This report affirms the findings of Aldridge and colleagues and documents the first report of metronidazole resistance among Bacteroides spp. in the United States. Trends in susceptibility testing showed increasing resistance to clindamycin, moxifloxacin, and ampicillin/sulbactam, with relatively stable resistance rates to carbapenems, and piperacillin/tazobactam.

Infections acquired in the intensive care unit (ICU) often occur during the treatment of critically ill patients, increasing their morbidity, mortality, and health care costs.^{1,2} Several studies suggest that the use of prophylactic antibiotic regimens such as selective decontamination of the digestive tract (SDD)³⁻⁶ and selective oropharyngeal decontamination (SOD) can reduce the incidence of respiratory tract infections and mortality in ICU patients.^{5,7,8} The SDD approach^{9,10} is directed toward the following: prevention of secondary colonization with gram-negative bacteria, *Staphylococcus aureus*, and yeasts through application of nonabsorbable antimicrobial agents in the oropharynx and gastrointestinal tract; preemptive treatment of possible infections due to commensal respiratory tract bacteria through systemic administration of cephalosporins during the patient's first 4 days in the ICU; and maintenance of anaerobic intestinal flora through selective use of antibiotics (administered both topically and systemically) without anti-anaerobic activity.¹⁰

BACKGROUND

The intestinal flora is highly diverse and consists primarily of anaerobic bacteria. Intact anaerobic flora is considered an important defense mechanism against intestinal colonization by potentially pathogenic microorganisms. The commensal flora of the oropharynx consists of hundreds of bacterial species, including enterococci and anaerobic bacteria, which are replaced by gram-negative bacteria during the first week of hospitalization in the ICU. Gastric acidity usually prevents bacterial overgrowth in the stomach. Yet, in ICU patients, reduced acid production due to underlying diseases, use of acid-modifying medication (stress ulcer prophylaxis), and intragastric administration of enteral nutrition (with a pH of 6) leads to a gastric environment that favors bacterial growth, especially of gram-negative bacteria.

Anaerobic bacteria grow well on the mucosa of the gut and actively line the epithelium.¹¹ Disruption of this layer by antibiotics that destroy the anaerobic flora may create a portal of entry for pathogenic microorganisms.

Combinations of nonabsorbable antibiotics have been used to selectively decontaminate the digestive tract and reduce the load of pathogenic aerobic microorganisms while maintaining the anaerobic flora. This concept was first investigated in mice⁹ and later developed into an infection prevention strategy for neutropenic leukemia patients, which the investigators called *selective decontamination of the digestive tract*, or SDD.^{12,13}

From Concept to Practice in the ICU

The earlier experience with SDD in leukemia patients suggested that some infections in ICU patients might have an endogenous source and could be prevented in the same way. After a 2-year observational microbiological study of trauma patients, an infection classification was proposed (Table 119-1) that included definitions for colonization and the use of SDD for infection prevention in trauma patients in the ICU.^{10,14,15} These studies resulted in the establishment of an SDD regimen consisting of the application of nonabsorbable antimicrobial agents in the oropharynx and gastrointestinal tract to prevent acquired colonization with gram-negative bacteria, *Staphylococcus aureus*, and yeasts, in combination with 4 days of intravenous administration of a third-generation cephalosporin to preemptively treat incubating respiratory tract infections with gram-positive and gram-negative bacteria. Topical and systemic antibiotics were selected based on their antibacte-

rial spectrum and presumed absence of activity on the anaerobic intestinal flora.^{14,15}

CLINICAL RESULTS

Earlier Studies

The first study of SDD in ICU patients was performed in 63 trauma patients, using a historical control group of 59 trauma patients.¹⁰ Because of its design and use of a historical control group, this study not only triggered many critical comments and editorials but also led to additional studies in more heterogeneous ICU patient populations, with different combinations of absorbable and nonabsorbable antibiotics, with or without parenteral antibiotics.^{3,16-18} The conflicting results of these clinical trials led to the conclusion that there was insufficient scientific evidence to recommend SDD as a routine infection control measure in ICU patients.¹⁹

Recent Studies

A single-center, prospective, controlled, randomized, unblinded study in 2003 reported significantly lower ICU and hospital-mortality rates (35% and 22%, respectively), shorter length of stay, and a lower incidence of antibiotic resistance in patients with an expected duration of mechanical ventilation of ≥ 2 days and/or expected length of stay in the ICU of ≥ 3 days and receiving SDD.^{4,20} A subsequent multicenter, controlled, crossover study using cluster randomization and identical inclusion criteria that compared SDD with SOD was performed in the Netherlands. SOD was included because of the hypothesis that the main effect of SDD—a reduction in the incidence of ventilator-associated pneumonia (VAP)—could be achieved by oropharyngeal decontamination only, without intestinal decontamination and without the routine prophylactic use of systemic antibiotics during the first 4 days of ventilation.^{7,8} The results of this first Dutch multicenter trial (DMT-I) with almost 6000 patients showed that SDD and SOD groups were associated with a reduction in mortality at day 28 of 13% and 11% relative to controls, respectively, corresponding to an absolute reduction of 3.5% and 2.9%.⁵ There were several noteworthy limitations to this study; in particular, as with most SDD studies, it was not blinded, so all physicians were aware of the treatment patient participants would receive. Because inclusion was based on several criteria, this created the possibility of selection bias. To minimize the occurrence of selection bias, patient eligibility and inclusion rates were monitored frequently and immediately followed by feedback to the participating investigators. Yet despite the use of these measures next to the objective inclusion criteria, there were baseline differences between the control and the two intervention groups. Patients in the intervention groups (SDD and SOD) were more frequently intubated, less likely to be surgical patients, and had a higher baseline APACHE score. Further, SDD patients were older compared to SOD and control patients.⁵

A second Dutch open cluster, randomized, crossover, multicenter trial (DMT-II: 12,000 patients) compared 12 months of SDD to 12 months of SOD. Again, there was a baseline difference, and there was no day-28 mortality difference between SDD (24.1%) and SOD (25.4%) (SDD vs. SOD: adjusted OR 0.96, 95% CI 0.88-1.06) and no difference in the length of stay.²¹ A Cochrane meta-analysis was published in 2009 on the effects of topical antibiotics (with or without systemic antibiotics) and its effects on mortality and the incidence of respiratory tract infections (RTI).⁶ This meta-analysis included 36 trials, with a total of

TABLE 119-1 Definitions

| | |
|---------------------------------|--|
| Colonization resistance | The strong protective effect of the endogenous anaerobic fraction of the intestinal microflora in resisting colonization by aerobe microorganisms along the alimentary canal. Suppression of the anaerobic flora increases the risk of overgrowth by gram-negative bacteria. |
| PPM | Potentially pathogenic microorganisms |
| SDD | Selective decontamination of the digestive tract is the selective elimination of PPM from the oral and intestinal flora by topical, nonabsorbable, antibiotics. |
| SOD | Selective oropharyngeal decontamination is the selective elimination of PPM from the oral flora by topical, nonabsorbable, antibiotics. |
| Primary endogenous infections | Caused by PPM with which the oropharynx and/or digestive tract of the patient was colonized at admission. These PPM are part of the "normal" flora of the patient. |
| Secondary endogenous infections | Caused by PPM with which the oropharynx and/or digestive tract of the patient was not colonized at admission but acquired during ICU stay |
| Exogenous infections | Caused by PPM not present at admission and developing without preceding colonization |
| Colonization | Presence of the same species of PPM in an organ system for more than 3 days (≥ 2 positive cultures) without signs of infection |

6914 patients (without DMT-I for the reasons described). The authors concluded the following:

1. In trials comparing a combination of topical and systemic antibiotics to controls, there was a significant reduction in both RTIs (16 studies; OR, 0.28; 95% CI 0.20-0.38) and mortality (17 studies; OR, 0.75; 95% CI, 0.65-0.87).
2. In trials comparing topical antibiotics alone to controls or comparing topical plus systemic to systemic alone, there was a significant reduction in RTIs (17 studies; OR, 0.44; 95% CI, 0.31-0.63) but not in mortality (19 studies; OR 0.97, 95% CI, 0.82-1.16).

This last conclusion contrasts the results of the DMT-I, which showed a significant reduction in mortality with the use of topical antibiotics in the oropharynx only.⁵

Another systematic review and meta-analysis published in 2014 compared SDD, SOD, and oropharyngeal chlorhexidine for the prevention of death and concluded that SDD had a favorable effect on mortality, with a less certain effect of SOD. Both were superior to chlorhexidine, with a remark that chlorhexidine might be associated with increased mortality.²²

The "what, when, and why" of the different parts of the SDD regimen as it is used in the latest studies are shown in Table 119-2.

MICROBIOLOGICAL EFFECTS OF SELECTIVE DECONTAMINATION

Decontaminating Effect

The DMT-I showed that the proportion of SDD patients colonized with gram-negative bacteria isolated from rectal swabs decreased from 56% at day 3 to 25% at day 8 and 15% at day 14. Oropharyngeal colonization rates with gram-negative bacteria decreased from 18% at day 2 to 4% at day 8 among SDD patients. The same trial showed a comparable decrease in oropharyngeal colonization rates with gram-negative bacteria in SOD patients from 20% at day 2 to 7% at day 8.⁵ These results are comparable to those reported in other studies.^{10,23,24} Further, it was shown that SDD could eradicate cephalosporin-resistant Enterobacteriaceae from the intestinal tract.²⁵

The positive effects of SDD (and SOD) on respiratory tract colonization and infection have been described extensively.^{4,6-8} The DMT-I showed significantly a lower incidence of ICU-acquired bacteremia during SOD and SDD for *S. aureus*, glucose-nonfermenting gram-negative rods (mainly *Pseudomonas aeruginosa*), and Enterobacteriaceae as compared to controls. The incidence of ICU-acquired candidemia was lower in the SDD group compared to either SOD or control groups.⁵ Patients receiving SDD had a lower incidence of ICU-acquired bacteremia with Enterobacteriaceae than those receiving SOD,^{5,26} a result that was confirmed by the DMT-II.²¹

Emergence and Selection of Antibiotic Resistance in Gram-Negative and Gram-Positive Microorganisms During Selective Decontamination

Enhanced selection of antibiotic-resistant microorganisms has been considered an important threat of SDD and SOD.²⁷ Consistent use of surveillance cultures as part of SDD and SOD protocols makes it possible to assess the efficacy of enteral decontamination and to detect the emergence of antibiotic-resistant pathogens early.

Gram-Negative Microorganisms

Several studies showed an overall decrease in antibiotic-resistant gram-negative microorganisms in patients receiving SDD, including a significant beneficial effect on colonization with resistant gram-negative bacteria such as *P. aeruginosa* resistant to ceftazidime, imipenem, and ciprofloxacin and other aerobic gram-negatives resistant to imipenem, ciprofloxacin, and tobramycin.^{4,18} Patients receiving SDD during the DMT-I had a lower incidence of ICU-acquired candidemia, bacteremia with Enterobacteriaceae, and bacteremia with highly resistant microorganisms (HRMO; according to Dutch guidelines²⁸) than those receiving SOD, all confirmed by the DMT-II except for candidemia.²⁹ Analysis of the rates of colistin resistance during SDD and SOD in DMT-I showed that during persistent intestinal carriage of gram-negative bacteria and during intestinal colonization with tobramycin-resistant gram-negative bacteria, the risk of acquisition of colistin resistant gram-negative bacteria and conversion rates to colistin resistance increased. The overall risk of acquisition of colistin-resistant gram-negative bacteria and conversion rates to colistin resistance were low.³⁰ A post hoc analysis in five Dutch ICUs using SDD or SOD over 7 years showed no increase in the prevalence of resistance against colistin or tobramycin.³¹ On the other hand, an increase in colistin resistance in extended-spectrum beta-lactamase (ESBL)-producing *Klebsiella pneumoniae* was reported when SDD was used to control an outbreak.³²

The incidence of candidemia and bacteremia caused by HRMO was low in both the DMT-I and -II, so whether the difference between SDD and SOD will translate into a difference in clinical outcome depends on the overall incidence of candidemia and bacteremia caused by HRMO, the appropriateness of empiric antimicrobial therapy in such patients, and the attributable effects of such events on the outcome and length of stay. These findings do not support the concern that the use of topical antibiotics, with or without systemic prophylaxis with third-generation cephalosporins, increases the prevalence levels of antibiotic resistance in gram-negative bacteria. This conclusion is supported by two 5-year prospective studies and a recent meta-analysis.³³⁻³⁵

Gram-Positive Microorganisms

Methicillin-resistant *S. aureus* (MRSA) and vancomycin-resistant *Enterococcus* (VRE) are highly prevalent in ICUs in many countries, unlike the Netherlands, where the last three major studies were carried out. The use of topical antibiotics for SDD or SOD is generally considered to be contraindicated in such settings, as such regimens may increase colonization and infection rates with these bacteria. More data are available on the effects of SDD or SOD in settings with high levels of MRSA.³³ In one study, a shift toward gram-positive organisms was detected after the introduction of SDD in trauma patients, including

TABLE 119-2 Selective Decontamination of the Digestive Tract Regimen

| WHAT | WHEN | WHY |
|---|--|---|
| BASELINE | | |
| Oropharyngeal application of 0.5 g of a paste containing polymyxin E, tobramycin, and amphotericin B, each in a 2% concentration* | 4 times daily until ICU discharge | Selective decontamination of the oropharynx |
| Administration of 10 mL of a suspension containing 100 mg polymyxin E, 80 mg tobramycin, and 500 mg amphotericin B via the nasogastric tube | 4 times daily until ICU discharge | Selective decontamination of the gut from stomach to rectum |
| Cefotaxime 1 g intravenously during the first 4 days of study (or other third-generation cephalosporins) | 4 times daily during the first 4 days | Preemptive treatment of primary endogenous infections |
| Avoidance of (systemic) antibiotics that might impair the colonization resistance (i.e., antibiotics with antianaerobic activity) | During treatment with SDD, until ICU discharge | Avoidance of penicillins, carbapenems, etc. No addition of antibiotics for patients with colonization without clinical signs suggestive of infection |
| Cultures of endotracheal* aspirates, oropharyngeal* and rectal swabs | On admission and surveillance cultures twice weekly | Determination of colonization pattern at admission and during treatment, including monitoring of effectiveness of SDD Detection of infection |
| Oropharyngeal care* | 4 times daily using sterile water or chlorhexidine† mouthwash, preceding application of oropharyngeal paste; includes brushing of teeth twice daily Clean visually contaminated oropharyngeal cavity with swab moistened with 1.5% hydrogen peroxide | Cleansing of mouth and teeth Removing residue of paste Preparing mouth for (next) application of paste |
| Use of normal hygiene guidelines* | Always | Preventing transmission of pathogens in the patient Prevention of (exogenous) cross-contamination and infections from and to other patients Control of outbreak |
| MODIFICATIONS FOR PATIENTS WITH | | |
| Tracheostomy* | 0.5 g of paste applied around the tracheostomy 4 times daily | Selective decontamination of the oropharynx |
| Duodenal tube or jejunostomy | Divide the 10 mL of suspension into 5 mL suspension via the gastric tube and 5 mL via the duodenal tube or jejunostomy | Selective decontamination of the gut from stomach to rectum |
| Colostoma or ileostoma | SDD suppositories (containing 100 mg polymyxin E, 40 mg tobramycin, and 500 mg amphotericin B) twice daily in the distal part of the gut | Selective decontamination of the gut from stomach to rectum |
| Documented cephalosporin allergy | Cefotaxime can be replaced by ciprofloxacin (twice daily 400 mg). | Avoidance of allergic reaction |
| MODIFICATIONS FOR PATIENTS WITH PERSISTENT RESPIRATORY TRACT COLONIZATION WITH YEASTS OR GRAM-NEGATIVE BACTERIA | | |
| If a surveillance culture (>48 h after admission culture) of the throat yields yeasts and/or gram-negative bacteria* | Increase application of oropharyngeal paste to 8 times daily until 2 surveillance cultures are negative. | Decolonization |
| If a sputum surveillance (>48 h after admission culture) culture yields yeasts* | Nebulize 5 mL (5 mg) amphotericin B 4 times daily until 2 sputum cultures are negative. | Decolonization |
| If a sputum surveillance culture (>48 h after admission culture) yields gram-negative bacteria* | Nebulize 5 mL (80 mg) polymyxin E 4 times daily until 2 sputum cultures are negative. | Decolonization |

*The SDD regimen from de Smet AM, Kluytmans JA, Cooper BS, et al. Decontamination of the digestive tract and oropharynx in intensive care patients. *N Engl J Med* 2009;360:20–31.

†Chlorhexidine was not used in the Dutch SDD-SOD trial (*N Engl J Med* 2009;360:20–31).

an outbreak and increased carriage rates with MRSA 2 years after the introduction of SDD.^{36,37} This shift was successfully addressed by implementation of control measures.³⁶ To prevent infections with MRSA, some investigators add vancomycin to the SOD or SDD regimen.^{7,38} When applied topically, vancomycin is not absorbed and reaches high concentrations in the intestinal tract. In a Spanish burn unit, SDD with topical vancomycin was associated with improved patient outcome and lower colonization rates with MRSA.³⁸ A disadvantage of such an approach might be the selection of VRE in ICUs where both pathogens are prevalent; however, such reports have not been published yet.

The results of the DMT-I indicate that both SDD and SOD are associated with higher rates of acquired respiratory tract colonization but not with higher rates of bacteremia caused by enterococci.

In ICU patients, enterococci will colonize all body sites (especially the skin) and contaminate the inanimate environment. Enterococci are now among the most frequent causes of hospital-acquired infections worldwide, and the proportion of infections caused by ampicillin-resistant enterococci (ARE) has increased substantially in Western countries, including the Netherlands.³⁹ In the United States, approximately 35% of all ICU-acquired enterococcal bacteremias are caused by VRE. The clinical relevance of ARE and VRE infections is unclear.

Widespread use of topical vancomycin in units with high levels of MRSA will increase the selective pressure for VRE. This factor should be carefully balanced against the benefits of treating SDD or SOD with vancomycin. In the United States, ICUs with high levels of MRSA frequently also have high endemic levels of VRE. In such settings,

the addition of oropharyngeal chlorhexidine oral washings and/or chlorhexidine body washings may help to control spread and bloodstream infections caused by VRE and MRSA.^{40,41}

Ecological Effects

During the DMT-I, surveillance cultures from the respiratory and intestinal tract were obtained each month on a fixed day from all patients present in the ICU, regardless of whether they were included in the study.⁵ These 18 point-prevalence studies in 13 ICUs allowed analysis of the effects of SDD and SOD on the bacterial ecology in these ICUs together. The effect of SDD (over a 6-month period) and SDD/SOD (combined over a 12-month period) on intestinal and respiratory tract carriage with gram-negative bacteria was determined by comparing results from consecutive point-prevalence surveys using intervention to consecutive point-prevalence data in the pre- and post-intervention periods.⁴² The average proportion of patients colonized with ceftazidime, tobramycin, or ciprofloxacin-resistant gram-negative bacteria in the intestinal tract decreased during the use of SDD in the ICU and increased again after discontinuation. During combined SDD/SOD, resistance levels in the respiratory tract were low ($\leq 6\%$) for all three antibiotics but seemed to increase gradually, with a significant increase only for ceftazidime resistance ($P < 0.05$). After discontinuation of SDD/SOD, the resistance levels increased to 10% or higher. Clearly, both SDD and SOD have marked ecological effects that are supported by the results of a 4-year ecological study published in 2014.⁴³ According to the DMT-II, SDD showed significantly lower rectal carriage of antibiotic-resistant gram-negative bacteria than did SOD.²¹ Further, a gradual increase in tobramycin resistance was observed during both the SOD and SDD periods, but more clearly during SDD; however, the incidence of acquired bacteremia with aminoglycoside-resistant GNB was lower in the SDD group than in the SOD group.²¹ Of note, some of these patients were in the ICU only briefly (and not receiving SOD or SDD), and the incidence of resistance in other hospital wards was unknown. An increasing incidence of resistance in the participating hospitals might have influenced these results.

Overall, the ecological effects (i.e., lowest resistance levels during interventions) corroborate the positive effects of SOD and even more of SDD on antibiotic resistance in individual patients.^{4,29}

Other Issues

Effectiveness of SDD in Specific Patient Groups

Evidence suggests that SDD might not be equally effective in all ICU-patient groups. In one meta-analysis, increased SDD efficacy was observed in surgical patients.¹⁷ Further, studies on the preoperative use of SDD suspension and other oral antibiotics in patients undergoing gastrointestinal surgery report lower rates of surgical site infections and anastomotic leakage.⁴⁴⁻⁴⁶ In a post hoc subgroup analysis of the Dutch multicenter study, different effects of SDD and SOD were found for surgical and nonsurgical patients.⁴⁷ Compared to controls, SDD was equally effective in decreasing 28-day mortality in surgical and nonsurgical patients and significantly decreased the duration of mechanical ventilation, ICU stay, and hospital stay among surgical patients. On the other hand, SOD appeared to be even more effective in reducing mortality in nonsurgical patients but was not associated with a decrease in day-28 mortality in surgical patients or in the duration of mechanical ventilation or length of stay in the ICU or hospital. These findings suggest that surgical patients benefit from the addition of the enteric and/or systemic component of the SDD regimen. However, the DMT-II did not show comparable effects between the SOD and SDD groups, possibly because of a different definition of “the surgical patient.”²¹ All in all, these results should be considered as hypothesis generating. Further studies are needed to confirm such observations. If confirmed, the results may help elucidate the mechanisms of the protective action of SDD and SOD in specific groups of ICU and other patients.

Hospital-Acquired Infections After Treatment with SOD and SDD

In the SDD study by De Jonge et al., the relative risk reduction in ICU mortality of 35% decreased to 22% at hospital discharge.⁴ Triggered by these findings, it was hypothesized that this reduction in survival benefit after ICU discharge might be related to an increased incidence of hospital-acquired infections (HAI) in patients who had received SDD in the ICU. Nested within the DMT-I, the incidence of HAI was prospectively monitored during the first 14 days after ICU discharge in all patients transferred to regular wards in two university hospitals.⁴⁸ Most HAI were in the respiratory tract, with a similar incidence and duration of infection in all three posttreatment study groups. The incidence of bloodstream infections was also similar in the three post-treatment groups, but the time until infection tended to be longer in the post SOD and post SDD groups compared to the post control group. On the other hand, the incidence of surgical site infections (SSI) increased in the postintervention groups. Considering the low rates of HAI, the overall low mortality rates after ICU discharge and the low prevalence of infections among those who succumbed after ICU discharge refute the hypothesis that discontinuation of SDD and SOD post ICU increases the infection rate and thus affects clinical outcomes.⁴⁸

Antibiotic Use and Cost-Effectiveness

De Jonge determined that the total cost of antibiotics, topical and systemic, was 11% lower in the SDD group than in the control group. This difference was primarily attributed to the decrease in the use of antibiotics such as ciprofloxacin, ceftazidime, imipenem, and antifungal treatment.⁴ These results were confirmed by the DMT-I, with a decrease of 12% and 10% in the use of daily defined doses of systemic antibiotics in the SDD and SOD groups, respectively, as compared to controls.⁵ The post hoc cost-effectiveness evaluation showed that both SDD and SOD were effective and cost saving in Dutch ICUs.⁴⁹

Adverse Events

Three patients are reported to have suffered large clots from accumulation of the buccally applied oral SDD/SOD paste, causing obstruction of the esophagus or jejunum. This complication can be prevented by regular and appropriate oral care.⁵⁰

KEY POINTS

1. Selective decontamination of the oropharynx (SOD) and the digestive tract (SDD) improves survival in ICU patients.
2. Both SDD and SOD lower the incidence of bacteremia, respiratory tract infection (RTI), and the use of systemic antibiotics. SDD reduces the incidence of bacteremia compared to that of SOD. Only SDD lowers the incidence of candidemia compared to controls.
3. No evidence supports the concern that the use of topical antibiotics with or without systemic prophylaxis increases the prevalence of antibiotic resistance to gram-negative bacteria. In particular, SDD decreases the rate of antibiotic resistance to gram-negative bacteria.
4. Both SDD and SOD are cost effective.
5. Larger and longer longitudinal studies are needed to determine the long-term effects of SOD and SDD on antibiotic resistance, with special attention to the changes in antibiotic resistance among gram-negative bacteria in surroundings with high antibiotic resistance levels and in combination with other topical agents such as chlorhexidine.

State-of-the-art meta-analysis. Provides a very good and thorough overview of SDD studies, concluding that a combination of topical and systemic antibiotics causes a significant decrease in RTIs (16 studies; OR, 0.28) and mortality (17 studies; OR, 0.75) compared to controls. Comparing topical antibiotics alone to control or topical plus systemic to systemic alone, there was a significant reduction in RTIs (17 studies; OR, 0.44) but not in mortality (19 studies; OR, 0.97).

de Jonge E, Schultz M, Spanjaard L, et al. Effects of selective decontamination of the digestive tract on mortality and acquisition of resistant bacteria in intensive care: a randomised controlled trial. *Lancet* 2003;362:1011–1016.

Prospective, randomized, controlled, single-center study on SDD in 934 ICU patients with an expected length of stay more than 72 hours and/or expected duration of mechanical ventilation more than

48 hours. The most important finding was a remarkable 34.7% relative reduction in ICU mortality for patients treated in the SDD ward. For these patients, the relative reduction in hospital mortality was 22.6%. In addition, SDD-treated patients had a shorter duration of ventilation, and total antibiotic costs were less for these patients. Furthermore, isolation of antibiotic-resistant gram-negative bacteria occurred more frequently among non-SDD patients.

de Smet AM, Kluytmans JA, Cooper BS, et al. Decontamination of the digestive tract and oropharynx in intensive care patients. *N Engl J Med* 2009;360:20–31.

First multicenter, cluster-randomized trial comparing SDD with SOD and control in groups (2000 patients per group). Both interventions significantly improved survival (absolute mortality reduction of 3.5% and 2.9%, respectively) and decreased the rate of bacteremia (ORs SDD versus control, 0.44; SOD versus control, 0.68; SDD versus SOD, 0.65).

Central venous catheters (CVCs) are inserted into about half of the ICU patients and are present for 65% of the patient-days. In Europe, the incidence density of CVC-related bloodstream infections (BSIs) ranges from 1 to 3.1 per 1000 patient-days.¹ In the United States, 15 million CVC-days are estimated to occur each year in ICU patients, as well as about 40,000 CVC-related BSIs, leading to a rate of more than 2 for 1000 CVC-days.² The attributable mortality of CVC-related BSIs ranges from 0% to 11.5%,³ and the excess ICU length of stay was estimated at 9-12 days.^{4,5}

In contrast to other nosocomial infections, a large fraction of the risk factors are device-related, suggesting that CR-BSI is largely preventable if rigorous policies are adopted. The education and training of healthcare workers and continuous unit-based improvement programs are essential.^{6,7} New technical developments will be discussed and put into perspective according to the available recommendations.

■ PATHOPHYSIOLOGY

Colonization of the catheter occurs by two main pathways: the extraluminal route and the intra-luminal route. The cutaneous entry site of the catheter is the predominant route of colonization for short-term CVCs (<15-20 days), whereas colonization via the endoluminal route resulting from hub contamination predominates for long-term CVCs.⁸ These main differences should be kept in mind when choosing between different diagnostic options and preventive strategies.

The occurrence of bacteremia caused by common skin organisms is a major criterion for the diagnosis of CR-BSI, although gram-negative *Enterobacteriaceae* and *P. aeruginosa* are often encountered, especially in case of femoral site of insertion.⁹

■ DEFINITIONS

Published guidelines for the diagnosis of CR-BSI are used worldwide. It is important to keep in mind available definitions to better interpret clinical evidence. Related definitions are summarized in Table 120-1.

■ DIAGNOSIS OF CATHETER INFECTIONS

Fever or erythema at the catheter entry site is nonspecific and usually of little help in diagnosing CR-BSI. Usually, when CR-BSI is suspected, the common practice in the ICU is to remove the CVC and to replace it at a new site. However, only about 15 to 25 percent of CVCs removed as such indeed proved to be infected upon quantitative tip culture.

Diagnostic Tests Performed After Catheter Removal

Qualitative broth culture has a high sensitivity but a very low specificity and is unable to distinguish contamination from infection. Quantitative culture techniques have been developed for investigating either the extraluminal part of the catheter (semiquantitative Maki's technique) or the extra- and intraluminal catheter.¹⁰⁻¹³ Overall, quantitative culture techniques appear more accurate than the semiquantitative ones.¹⁴

One clinical and one experimental study showed that the sensitivity of catheter culture^{15,16} might be decreased by the previous use of antimicrobials. This point should be kept in mind when interpreting nega-

tive or borderline culture results and emphasize the need for diagnostic tests (blood and catheter cultures) before starting new antimicrobials.

Diagnosis of CR-BSI with the Catheter in Place

In case of severe sepsis, the catheter should be systematically removed.¹⁴ The diagnosis of catheter-related BSI is then performed as described above. However, most of the suspected catheter-related infections are not life threatening. Diagnostic techniques that allow an accurate diagnosis while keeping the catheter in place are attractive options in these cases.

Quantitative Culture of the Catheter Exit Site

Quantitative culture of the catheter exit site reflects the extraluminal contamination pathway. Bouza et al.¹⁷ have confirmed the good negative predictive value of negative skin surface culture for predicting catheter colonization (NPV, 90.6%) or CR-BSI (NPV, 99.2%).

In case of suspicion of CRI, such culture tests rule out this diagnosis, thereby preventing unnecessary catheter replacement. However, routine surveillance culture is useless, as positive cutaneous culture is closely related to cutaneous clinical signs at the insertion site.¹⁸

Quantitative Blood Culture

Simultaneous samples drawn through the catheter and through a peripheral vein without removal or exchange of the catheter are more accurate in predicting CR-BSI. The time to positivity of a blood culture is highly related to the bacterial concentration in the milieu. Therefore, measuring differences in the time to positivity of hub blood as compared to peripheral blood cultures has been proposed.¹⁹ Using a cutoff of 120 minutes, sensitivity and specificity were greater than 90%.¹⁹ Theoretically, this technique only explores the intraluminal route of infection, but recent reports suggest that it should be used for both short- and long-term CR-BSI.¹⁹⁻²¹ Aspiration is technically impossible in one-fourth of the cases.²² Furthermore, each lumen may represent a source of infection. One study reported that sampling one out of three lumens of the catheters missed 37.3% of the CR-BSI.²³

■ PREVENTION

Guidelines for CR-BSI prevention have been recently updated.^{7,24} Such guidelines are based on two categories of studies: those applying multi-module programs to improve general infection control measures when using catheters, such as surveillance, education, quality management strategies, and those testing new biomaterials, antiseptic dressings, and catheter locks. Key points are summarized in Table 120-2.

Catheter Insertion

One important part of prevention concerns catheter insertion.

Sterile Barrier Precautions and Skin Antisepsis

Full barrier precautions using sterile gloves, a long-sleeved sterile gown, mask, cap, and large sterile sheath drape during catheter

TABLE 120-1 Definitions

| | DEFINITION | COMMENTS |
|---|--|---|
| Catheter tip colonization | Positive culture of the catheter tip that grew to ≥ 15 cfu/mL (semiquantitative), 10^2 cfu/mL (quantitative sonication), or 10^3 cfu/mL quantitative vortexing. | Qualitative culture should no longer be used. |
| Exit-site infection | Tenderness, erythema of site induration >2 cm | Positive culture of exudate confirms the exit-site infection microbiologically |
| Catheter-related bloodstream infection (CR-BSI) | One positive blood culture obtained from a peripheral vein and clinical manifestation of infection and (1) catheter tip colonization or (2) a differential time to positivity of more than 120 min and no obvious source of bacteremia except the catheter | Simultaneous quantitative culture from a peripheral vein and the catheter of 5:1 ratio is rarely used. NB: exclusion of other sources of infection reveals important variability in the final classification in ICU patients. Purulence of the catheter exit site strongly implicates the catheter as the source of infection. |
| Central line–associated bloodstream infection (CLA-BSI) | One positive blood culture and clinical manifestation of infection in a patient with a catheter in place with no other source of bacteremia except the catheter | Easy-to-collect definitions for epidemiologic purposes. Exposed to an overestimation of the BSI due to catheter infection, especially in ICU and oncohematological patients |
| Catheter-related clinical sepsis | Clinical manifestation of infection that disappears within 48 h of catheter removal and a positive catheter tip culture and no other obvious treated source of infection | Represent 30%-50% of catheter-related infections with general manifestations. Not easy to collect routinely but may need antimicrobial treatment (see text). |

TABLE 120-2 Main Recommended Strategies for Prevention of CR-BSI in ICU**STRUCTURE AND PROCESS OF CARE**

Adequate nurse-to-patient ratio
 Use only trained personnel who demonstrate competence for catheter insertion and maintenance
 Educate, assess knowledge, and audit adherence to guidelines of ICU HCWs
 Conduct a continuous quality-improvement program based on recommendations and adapted locally
 Organize a follow-up of the institution's process of care and CRBSI rate
 Participate in a surveillance network

CATHETER INSERTION

Hand hygiene
 Full barrier precautions for CVC insertion
 Preparation of cutaneous site with chlorhexidine
 Subclavian rather than jugular or femoral access (should be weighed against the risk of mechanical complications)
 Avoid subclavian access for dialysis catheters
 Subcutaneous tunnelling for internal jugular or femoral short-term CVCs*
 Ultrasound guidance to reduce number of cannulation attempts and mechanical complications for jugular and femoral access
 Use a sterile sleeve for all pulmonary artery catheters
 Do not routinely replace CVCs (even using guidewire exchange procedure)
 Chlorhexidine-sulfadiazine impregnated for short-term CVCs only if the level of CR-BSI is high despite implementation of a comprehensive strategy to reduce the rate of CR-BSI

CATHETER MAINTENANCE

Immediate dressing change if loosened, soiled, or moistened
 Remove catheters as soon as possible after intended use
 Daily visual inspection of the catheter site
 Sterile transparent or gauze dressings for CVCs
 Gauze when blood is oozing from the insertion site
 Chlorhexidine-impregnated gels or chlorhexidine sponge dressings should be used to reduce CRBSI from arterial catheters and CVCs
 Replace tubing used to administer blood products and lipid emulsions (including propofol) within 24 hours of initiating the infusion
 Replace administration sets no more frequently than at 4-day intervals, but at least every 7 days

insertion is an essential measure for preventing CR-BSI and must be a standard method during central venous and pulmonary catheter insertion. The potential of hand rubs with aqueous alcoholic solution to improve the compliance and tolerance of hand cleansing in the operating room has been reported, and its use could be extended to CVC insertion precautions.²⁵

Chlorhexidine solution is superior to aqueous povidone iodine (PVI) solution for cutaneous antisepsis. However, most studies compared 2% chlorhexidine or chlorhexidine-alcohol preparation to the regular PVI solution.²⁶ Alcohol acts in synergy with both chlorhexidine and PVI. It should be kept in mind that PVI possesses broad-spectrum activity and very rare intrinsic or acquired resistance of bacteria or fungi,²⁷ but its maximal efficacy is only reached after 2 minutes of application. A cluster-randomized study compared 5% povidone/70% ethanol to the regular 10% PVI. This study showed that alcoholic povidone decreased catheter colonization (OR, 0.38; 95% CI, 0.22-0.65) and catheter-related infection (OR, 0.34; 95% CI, 0.13-0.91) but failed to demonstrate a significant decrease in CR-BSI.²⁸

One monocenter randomized trial and one before-after study found that an alcoholic-CHG antiseptic is superior to 5% alcoholic-PVI in terms of catheter colonization.^{29,30}

One prospective cohort study found no difference in catheter colonization by CR-BSI between 0.5% alcoholic chlorhexidine and 2% aqueous chlorhexidine.³¹ A 2% alcoholic chlorhexidine solution is now available, but, considering its high cost as compared to that of the 0.5% alcoholic solution, the potential benefit of the 2% alcoholic chlorhexidine should be further demonstrated. A large RCT comparing 5% alcoholic-povidone iodine and 2% alcoholic-CHG will be available soon (CLEAN study; Clinicaltrial.gov NCT 01629550).³²

The suggested CHG superiority is probably based on its rapid bactericidal activity. The spectrum of CHG is narrower than the spectrum of PVI (particularly for sporulated microorganisms, *Mycobacterium* sp., and viruses). Increases in MIC to CHG have been shown for gram-negative bacteria (*Pseudomonas*, *Proteus*, and *Providencia* spp.), especially after CHG skin preexposure.³³ Less susceptible *Acinetobacter*, *Klebsiella pneumoniae*, and *Enterobacter* have also been recovered in hospital gram-negative flora.³⁴ Finally, acquired resistance has been found in methicillin-resistant *Staphylococcus aureus* (MRSA) and extended-spectrum beta-lactamases Enterobacteriaceae (ESBLE).²⁷ In vitro resistance profiles are not presently associated with clinical consequences, but we should be concerned about the extensive use of CHG and the absence of available alternatives.

Other solutions have been tested recently. Octenidine, a 0.1%-propanolol solution, is superior to ethanol in reducing catheter colonization (7.9 vs. 17.8%; $P = 0.009$).³⁵ Data comparing octenidine and CHG are not available.

Catheter Insertion Site

Central venous catheter insertion is required in many critically ill patients. Selection of the insertion site should be based on both the

ease and the risks of the procedure. These latter include infection, thrombosis, and mechanical complications. The choice of the best central venous access for a particular patient is based on the rate and severity of failures and complications.

Subclavian access should be preferred for infection control purposes,³⁶ although other factors (potential mechanical complications, thrombosis, operator experience) should be considered. Internal jugular and femoral access are associated with similar rates of infection, although the femoral route is associated with a higher colonization rate if the catheter is maintained for more than 5 days.³⁷

The use of femoral catheters is associated with a higher rate of thrombosis and should probably be restricted to thin patients for whom the mechanical complication of other access (i.e., pneumothorax or hemorrhage) would be unacceptable.

In the ICU, if femoral or internal jugular access is unavoidable, it should be kept in mind that catheter tunneling decreases the risk of CR-BSI.^{38,39}

Ultrasound-Guided Placement

The use of US guidance has been promoted to decrease the risks of failure and immediate complications of catheter insertion. This technique may confer advantages for jugular internal insertion.⁴⁰ This method decreased the rate of internal-jugular failed insertion and mechanical complications.⁴¹ The impact of US guidance on infection is uncertain.⁴² In hospitals where ultrasound equipment is available and physicians have sufficient training, the use of US guidance should be routinely considered before internal jugular CVC placement. Data concerning femoral and subclavian access are insufficient to draw definite conclusions.

Antithrombotic Prophylaxis

A close relationship has been demonstrated between catheter thrombosis and infection.^{43,44} A fibrin sheath surrounding the catheter enhances catheter colonization.⁴⁵ Recently conducted clinical trials suggest that heparin use reduces catheter-related infections. A randomized, double-blind study of critically ill children reported that heparin-bonded catheters reduce thrombosis (0 vs. 8%; $P = 0.006$) and the rate of positive blood cultures (drawn through the catheter) (4 vs. 33%; $P = 0.0005$).⁴⁶ Although heparin may be beneficial for decreasing the risk of catheter infection in bone marrow transplant patients,⁴⁷ its impact on ICU patients remains to be evaluated. The potential benefits of heparin or heparin-coated catheters might be balanced by the risk of heparin-induced thrombocytopenia.

Catheter Care: Replacement, Dressings, and Tubing

Repeated catheterization increases the risk of catheter infection.⁴⁸ This finding, together with randomized studies, argues in favor of avoiding any routine replacement of CVCs for catheters that are functioning and have no evidence of local or systemic complications. This conclusion is probably different for Swan-Ganz catheters and arterial catheters, where the daily risk of infection might increase with the duration of catheter maintenance.⁴⁹

Physicians and nurses should assess a patient's need for an intravascular catheter on a daily basis. Semipermeable transparent dressings are widely used and allow continuous observation of the skin insertion site and reduce the risk of extrinsic colonization. Gauze dressing is preferred if blood is oozing from the catheter insertion site. Catheter dressings should be changed immediately if the dressing becomes damp, loose, or soiled. We found that two-thirds of the dressings in the ICU have come loose before the planned removal date. Dressing disruption occurs more frequently if subclavian access is not used. The risk of CRI and CR-BSI increased more than threefold after the second dressing disruption and more than tenfold if the final dressing was disrupted.⁵⁰ The rhythm of scheduled dressing changes in the

ICU could be safely increased to 7 days provided soiled or nonadhered dressings are changed immediately.⁵¹

Systematic regrowth of cutaneous flora occurs under the transparent dressing, even after careful disinfection, because bacteria migrate from the derma to the epiderma. Epidermal regrowth of microorganisms is prevented by chlorhexidine-impregnated dressings. Both CHG-impregnated sponges and CHG-gel dressings are associated with a 60% decrease in the risk of catheter infections, including CR-BSIs.^{51,52} These findings were confirmed by a recent meta-analysis.⁵³ CHG-impregnated sponges and CHG-gel dressings were responsible for contact dermatitis in adults, with a rate of less than 10/1000 catheters without any recovered systemic reactions, but are discouraged for use in low-birth-weight infants (≤ 1000 g), where the rate of contact dermatitis was 15.3%.⁵⁴

It is recommended that tubings be replaced at least no more frequently than 96 hours but at least every 7 days.⁵⁵ A large, randomized study comparing tubing replacement every 4 versus every 7 days is ongoing in Australia.⁵⁶ Nevertheless, tubings used to administer blood, blood products, or lipid emulsions (including propofol infusions) should be replaced within 24 hours.⁵⁷

Many needless intravascular connector valves have been introduced into clinical practice to minimize the risk of needlestick injury. After disinfection of the connections, the microbial contamination of these systems is lower than that of the three-way stopcocks with caps.⁵⁸ However, in cohort studies, these systems are frequently shown to be contaminated after the common 3- to 5-second alcohol disinfection and therefore are frequently inadequately disinfected. Moreover, the devices are most often opaque, making it impossible to verify whether they have been properly flushed. These points explain why these devices have been repeatedly associated with outbreaks of bloodstream infections.⁵⁹⁻⁶¹ A large epidemiologic study involving five hospitals strongly suggested that these systems increase the risk of central line-associated infections.⁶² Overall, any excessive manipulation of CVCs independently increases the risk for CR-BSI and must be avoided.⁷

Antimicrobial-Coated or -Impregnated Catheters

The efficacy of catheters impregnated with chlorhexidine and silver sulfadiazine was tested in many randomized studies in the 90s. New chlorhexidine-sulfadiazine-impregnated catheters are now available that have a long half-life impregnation at the internal and the external surface. A meta-analysis of five randomized controlled trials has shown this catheter to halve the risk of CR-BSI (OR, 0.51; 95% CI, 0.56-1.00).⁶³ However, this study found significant heterogeneity between study results. More important, the pooled level of CR-BSI in the control groups was unacceptably high in two studies (7.2% and 14%). Therefore, the use of chlorhexidine-silver-sulfadiazine catheters should be proposed when the rate of infection is high despite adherence to other strategies such as maximal barrier precautions and implementation of an educational program. As acceptable incidence rates are below 1 CR-BSI per 1000 catheter-days, the use of such impregnated catheters is not standard practice. Other catheters impregnated with oligon, silver zeolite, carbon, and platinum have been tested, but their efficacy has not been proven.⁶³

Catheters impregnated intraluminally and extraluminally with minocycline-rifampin reduce the risk of CR-BSI as compared to polyurethane catheters and to externally coated chlorhexidine-silver sulfadiazine-impregnated catheters (OR, 0.23; 95% CI, 0.14-0.40).⁶⁴ Its use decreases the risk of CR-BSI as compared to controls (five studies in ICU; OR, 0.26; 95% CI, 0.15-0.47).⁶³ However, despite eight randomized, controlled trials, no clear conclusion could be drawn regarding the effect of the use of rifampin-minocycline-impregnated catheters on the development of antimicrobial resistance or on the selection of resistant flora and *Candida* spp.^{65,66} A large, monocenter, prospective 7-year follow-up of 9200 catheters (more than 500,000 catheter-days) failed to reveal the emergence of bacterial resistance among staphylococcal species.⁶⁷

Antibiotic or Antiseptic Lock Solutions

The prophylactic use of systemic antibiotic at the time of catheter insertion has not proven to be effective in reducing the incidence of CR-BSI and is strongly discouraged.

Use of an antiinfective lock requires that the catheter not be used during a certain period of time. This method is effective in preventing the endoluminal route of contamination, theoretically achieving antiinfective concentrations sufficient to kill organisms embedded in the biofilm, although its role in preventing short-term CR-BSI in the ICU is limited to catheters not used continuously (such as hemodialysis catheters⁶⁸ or PICCs in neonates). In a recent meta-analysis, the use of antimicrobial lock solutions led to a 69% reduction in the CLABSI rate (RR, 0.31; 95% CI, 0.24-0.40) and a 32% reduction in exit-site infection rate (RR, 0.68; 95% CI, 0.49-0.95) compared to heparin.⁶⁹ However, a significant publication bias was observed. Chelators such as citrate have an anticoagulant activity similar to heparin, increase the activity of antimicrobial drugs against organisms embedded in biofilm, and are superior to heparin in hemodialysis catheters.⁷⁰

Many antimicrobials, including vancomycin, teicoplanin, daptomycin, gentamycin, cephalosporins, and minocycline, have been tested for lock therapy with interesting results. However, in my opinion, to prevent CR-BSI, use of an antibiotic-antiseptic lock should be limited to the administration of substances that cannot be administered parenterally.

Ethanol lock solutions were also evaluated.⁷¹ They were found to be effective at concentrations greater than 20% and to inhibit biofilm formation even if left in place only 2 minutes (>50% ethanol).⁷² No interactions with catheter structures have been observed with concentrations below 90%. Recent RCTs performed outside the ICU provide conflicting results.^{73,74} The flush of the ethanol lock was associated with facial flushing (40%), altered taste (40%), and dizziness (50%) and should be strongly discouraged. Souweine et al. recently found that a 2-minute 60% ethanol lock does not decrease the rate of CR-BSI in hemodialysis catheters of ICU patients.⁷⁵

Impact of Continuous Quality-Improvement Programs

A comprehensive unit-based safety program that includes staff education, identification of and learning from defects, assignment of a manager to lead the program, and implementation of teamwork tools is essential to all general safety programs.^{76,77} Evidence must be translated into practice by creating a checklist, identifying local barriers to implementation, measuring performance, participating in a global network,⁷⁸ and ensuring that all health care workers (HCWs) receive the data. The general components of a unit-based safety program should easily be applied to control CR-BSI. The designation of a program leader is also a key factor for success.

Prevention and control of the spread of multiresistant bacteria, hand hygiene, and surveillance of nosocomial infections should be implemented at first. HCWs should then focus on several established methods directed at preventing contamination of the catheter. Proposed categories of practice should be developed using available recommendations and adapted locally: (1) improve hand hygiene compliance; (2) preferential use of subclavian access if possible; (3) use antiseptic solution containing alcohol; (4) inspect the insertion site daily; (5) immediately change unstuck soiled or moistened catheter dressings; (6) remove catheters immediately when no longer prescribed. These clear recommendations must be constantly reinforced to prevent frequent violations in routine practice.^{79,80}

Importantly, the positive effects of educational programs can be sustained if staff members are involved in designing the measures included in the program and all new nurses, residents, and fellows undergo an introductory in-service training program.⁸¹

Many success stories were published from 2002 to 2010 using these recommendations, most of which were observed in ICUs.⁸²⁻⁸⁶ While I personally believe that a zero-level infection rate could not be reached

and is a dangerous and counterproductive goal,⁸⁷ the implementation of bundles of care (adapted locally) combined with reinforcement of a safety culture is the necessary first step for improvement.

MANAGEMENT OF CATHETER-RELATED INFECTIONS

Catheter Removal or a More Conservative Attitude?

If catheter infection is suspected, the diagnostic strategy must be to change the catheter or use a more conservative strategy. The physician's attitude must be guided by the ease of a new catheter insertion, the immune status, the severity of the underlying illness of the patient, and the severity of the clinical sepsis. In this field, relevant data are very rare, as there are very few randomized studies and there are uncontrolled biases in most of the reported cohort studies. Cautious decisions about catheter removal and the type and length of antibiotic therapy should be made after each case is examined in light of these variables.

In case of septic shock or severe sepsis of undetermined origin or when frank local signs of infection are found, the catheter should be removed. In the absence of severe sepsis or local signs, two conservative strategies might be proposed, especially when a new catheter insertion is hazardous: (1) to change the catheter over a guidewire (GWX) or (2) to perform the watchful waiting strategy,⁸⁸ preferentially with catheter exit site culture (high negative predictive value) with paired blood cultures (high positive predictive value).

When conservative strategies have been initially decided, the decision of catheter removal mainly depends on microorganisms and on the evolution of the patient's state during the first 48 hours.

If blood cultures recover *S. aureus*, enterococci, gram-negative bacilli, or fungi, the catheter should be removed.^{14,89} For coagulase-negative staphylococci, catheters should generally be removed if blood culture contamination is ruled out on the basis of multiple positive culture results with at least one blood culture drawn from a peripheral vein.

Overall, conservative strategies are always risky in critically ill patients. After a decision is made, patients must be cautiously monitored. The catheter must be removed in case of a complicated course suggested by persistent fever or bacteremia longer than 3 days. If GWX occurs in the setting of an infection, the newly placed catheter should be removed. The timing of antimicrobial therapy in such cases has not been studied. Antimicrobial therapy instituted just before GWX might decrease the risk of infection at the new CVC.

Antimicrobial Therapy

When catheter BSI is associated with severe sepsis or shock, antimicrobial therapy must be administered immediately, together with catheter replacement. Probabilistic treatment should include vancomycin, a broad-spectrum β -lactamin with activity against *P. aeruginosa*, and an aminoglycoside. In case of previous *Candida* colonization or high risk thereof, antifungal therapy should be started, preferably with an echinocandin.

Treatment must be deescalated according to the results of catheter-tip cultures and blood cultures. In case of catheter-related BSI with positive blood cultures, the duration of treatment should be at least 14 days for uncomplicated (regression of septic signs and bacteremia <3 days, no persistent infectious site) infections with *S. aureus*, *Pseudomonas* spp., *A. baumannii*, and *Candida* spp. For uncomplicated CRI caused by other microorganisms, antimicrobial therapy should not exceed 7 days if the catheter has been removed. *Staphylococcus lugdunensis* should be treated in a similar manner to *S. aureus*.

In some rare circumstances, catheter salvage therapy might be proposed in the ICU, especially for long-term catheters inserted before the ICU stay. This treatment should only be considered in the absence of

severe sepsis and when *Candida* spp. and *S. aureus* (and probably *Pseudomonas* spp. or *A. baumannii*) are not the responsible microorganisms. Compared with parenteral therapy alone, antibiotic lock therapy was significantly more likely to result in catheter salvage. The fact that the catheter needs to be unused during the antibiotic lock process limits its potential usefulness in the ICU.

There are few reports in the literature to guide clinicians regarding the use of antimicrobial therapy for patients whose catheter tip cultures reveal significant growth in the absence of culture-proven bacteremia or fungemia. In case of clinical catheter-related sepsis, available data suggest that patients with a positive tip culture with *S. aureus* but without demonstrated bacteremia within 24 h after intravascular catheter removal had a 10% to 39% chance of subsequent *S. aureus* bacteremia if they did not receive immediate antistaphylococcal antibiotics. Similar results have been found for *P. aeruginosa*⁹⁰ and extensively resistant *A. baumannii*⁹¹ and to a lesser extent for *Enterococcus* spp. and *Candida* spp.⁹² Treatment within 24 h after intravascular catheter removal led to an important decrease in the incidence of subsequent bacteremia. All these retrospective studies suffer from important methodologic flaws and do not demonstrate that subsequent BSI is directly related to the positive catheter tip culture. While awaiting new studies, it seems reasonable to prescribe a short (7 days) course of antimicrobials to critically ill patient with sepsis whose catheters reveal significant growth of *S. aureus*, *P. aeruginosa*, *A. baumannii* or *Candida* spp., especially in immunocompromised patients or patients with heart valve disease. If the catheter tip culture grows coagulase-negative staphylococci or *Enterobacteriaceae*, catheter removal with no antimicrobial treatment might be sufficient. On the contrary, when a conservative approach has been chosen and the blood culture drawn through the catheter is positive, antimicrobial therapy should probably be given.

Complicated Courses

Relapse, continuous fever, or bacteremia despite removal of the catheter is consistent with a persistent focus of infection. This condition implies the need for prolonged or modified antimicrobial treatment and an active search for a catheter-related infection of another vascular line infection, metastatic abscess, septic thrombophlebitis, or endocarditis.¹⁴

Failure caused by poor pharmacokinetic-pharmacodynamic properties of the antimicrobial are mainly encountered when treating methicillin-resistant staphylococci with glycopeptides.

The volume of distribution of hydrophilic antimicrobials is always elevated in cases of septic shock and might explain the failure of treatment with β -lactams or vancomycin.⁹³ Therefore, therapeutic drug monitoring for the pharmacokinetic optimization of antimicrobials doses, particularly vancomycin, is strongly recommended in these situations.⁹⁴ Through level of vancomycin of 15 to 20 mg/L (or even 20 to 25 mg/L with *S. aureus* endocarditis) should be reached to obtain a C_{min}/MIC ratio of more than 5. Daptomycin might be an alternative of choice,⁹⁵ particularly when the MIC to vancomycin reaches 1.5 mg/mL.⁹⁶

In patients with *S. aureus* CR-BSI and persisting fever or bacteremia, transesophageal echocardiography should be used to rule out an endocarditis, and the treatment duration should be extended to at least 4 weeks of intravenous therapy with an active agent.

An infected intravascular thrombus after catheter removal may explain the persistence of severe sepsis despite adequate antibiotic therapy. In general, the most common infecting organism is *S. aureus*; less common pathogens includes *Candida* spp. and gram-negative bacilli.

The optimal choice and duration of therapy are based on retrospective studies and expert recommendations. A 4- to 6-week antibiotic treatment should be given. Although data from comparative trials are required to draw definitive conclusions, the available evidence suggests that the administration of heparin should be considered early in the management of patients with septic thrombophlebitis.⁹⁷ Surgical excision of the vein is rarely needed and should be limited to patients with purulent superficial veins or patients in whom the infection extends beyond the vessel wall, as well as cases in which conservative therapy has failed.

CONCLUSION

Catheter-related bloodstream infection is a leading type of nosocomial infection, particularly in ICUs, and the most frequent cause of hospital bacteremia. Although CR-BSI has milder consequences than other bacteremic infections, it is a typical device-associated iatrogenic infection and therefore highly preventable if rigorous policies are adopted. CR-BSI should be one of the main targets of a quality improvement program. The management of CR-BSI in the ICU most often requires catheter removal, although a more conservative strategy should be attempted in the absence of severe sepsis or septic shock.

KEY POINTS

1. Catheters are the leading source of bloodstream infections in critically ill patients.
2. Such infections are oversuspected because diagnostic signs are not specific enough, resulting in unnecessary catheter removal.
3. A conservative approach might be attempted in mild infections, while the catheter should always be removed in cases of severe sepsis or septic shock.
4. Comprehensive, unit-based improvement programs are now effective in decreasing the rate of CR-BSI. Rates of CR-BSI higher than 1 per 1000 catheter days are no longer acceptable.
5. A locally adapted checklist of preventive measures should include cutaneous antisepsis with alcoholic preparation, maximal barrier precautions, a strict policy of catheter maintenance, and ablation of useless catheters.
6. Antiseptic dressings and, to a lesser extent, antimicrobial-coated catheters, can be added to the prevention strategies if the level of infections remains high despite implementation of a prevention program.
7. In case of persistence of fever or positive blood culture after 3 days despite adequate antimicrobial therapy and catheter removal, endocarditis or thrombophlebitis should be ruled out.

INCIDENCE

Septic shock is a form of acute circulatory shock that occurs secondary to severe infection. The incidence of septic shock may be rising, partly related to medical progress that allows individuals to survive longer, resulting in increased numbers of older, debilitated, or immunocompromised patients passing through the intensive care unit (ICU). Some 15% of ICU patients develop septic shock at one time or another, and the mortality rate is close to 50%.^{1,2} Somewhat lower mortality rates have been reported in some trials evaluating the effects of new therapeutic interventions, but such studies include a number of exclusion criteria that are often associated with high mortality rates—cirrhosis, immunosuppression, and “do-not-resuscitate orders,” for example—so it is perhaps not surprising that mortality rates are lower in these therapeutic trials than in “real life.”

ETIOLOGY OF SEPTIC SHOCK

Septic shock is most often bacterial, but it can also be caused by a fungal or parasitic infection. In one-third of patients, no infectious agent is identified.^{1,2} About half of the infections are nosocomial in origin. Although an infection can arise anywhere, the lung is the most common source of infection (40%), followed by the abdomen (20%), indwelling venous and arterial catheters and primary bacteremias (15%), and the urinary tract (10%).^{1,2}

PATHOPHYSIOLOGY OF SEPTIC SHOCK

The pathophysiology of septic shock is complex. Essentially, the systemic sepsis response starts with the recognition of an invading organism or its toxins. Among the bacterial factors, one of the best known toxins is lipopolysaccharide, which is part of the outer gram-negative bacterial membrane, but other bacterial-derived factors include lipoteichoic acid and peptidoglycan. In certain cases, essentially infections involving *Staphylococcus aureus* or β -hemolytic group A *Streptococcus*, the formation of superantigens results in toxic shock syndrome.

The early humoral response involves the complement and contact (kinin-kallikrein) systems. Immune cells, principally monocytes/macrophages and polymorphonuclear neutrophils (PMNs), are not only able to recognize pathogenic agents and their products so they can phagocytose and destroy them but also release a series of mediators that can activate other cells. Among cell membrane receptors implicated in the recognition of pathogenic agents are the so-called Toll-like receptors. In response to cellular stimulation, intracellular signaling is activated, resulting largely in the activation of transcriptional factors, including nuclear factor kappa B, which in turn are responsible for the initiation of proinflammatory reactions. A number of cytokines, two of the key players being tumor necrosis factor alpha (TNF- α) and interleukin (IL)-1 that interact synergistically, are released by macrophages and other cells. TNF- α and IL-1 are particularly important proinflammatory cytokines whose administration in animals can reproduce all features of septic shock including hypotension and development of multiple organ failure. A host of secondary mediators including lipid mediators, oxygen free radicals, proteases, and arachidonic acid metabolites are also released by macrophages, PMNs, and other cells. Vasodilator substances such as nitric oxide (NO) and prostaglandins are released by endothelial cells and are responsible for the early hemodynamic changes of sepsis. NO, in particular, is a

powerful vasodilator acting on vascular smooth muscle. Increased NO production is essentially due to the induction of inducible NO synthase by proinflammatory cytokines. The formation of large quantities of NO can also have secondary toxic effects on cells. NO can block mitochondrial respiration, directly by inhibiting cytochrome a,a3 and reacting with superoxide radicals, resulting in the production of peroxynitrite, which inhibits various phases of mitochondrial respiration.³ These effects result in depletion of cellular adenosine triphosphate and potentially have detrimental effects on cell function. It is important to note that the inflammatory response also causes release of vasoconstrictor substances including thromboxane and endothelins.

Other effects of the inflammatory reaction that accompanies septic shock include expression of adhesion molecules on vascular endothelium and circulating cells (platelets, PMNs, and monocytes), allowing adhesion of activated leukocytes and their migration to subendothelial tissues. Alterations in intercellular endothelial junctions result in increased capillary permeability and generalized edema. Alterations in coagulation and fibrinolysis complete the picture, with proinflammatory mediators creating a procoagulant state. Briefly, the activation of tissue factor on the surface of various cells, particularly monocytes and endothelial cells, initiates the coagulation system.⁴ In addition, sepsis causes a significant reduction in plasma levels of natural anticoagulants such as protein C, protein S, and antithrombin by reducing their synthesis and increasing their consumption and clearance. Thrombolysis is also stimulated with an increase in the levels of plasminogen activator inhibitor-1. The net result is a balance in favor of procoagulant processes, often leading to disseminated intravascular coagulation and participating in the microcirculatory disorder that leads to multiple organ failure and death in many patients with severe sepsis.

During the sepsis response, antiinflammatory mediators including IL-4 and IL-10 are also released, which limit the effects of proinflammatory mediators and can lead to a state of relative immunosuppression sometimes called *immunoparalysis*.⁵ Many patients are already immunosuppressed when sepsis is diagnosed.⁶

CLASSIFICATION

Patients with septic shock may be classified according to the letters *PIRO*⁷:

P = Predisposing Factors

Each patient has specific characteristics. For example, an individual receiving long-term immunosuppressant therapy requires a different approach than someone who was previously healthy. Factors associated with lifestyle, such as alcoholism, may influence the course of septic shock.⁸ Patient age and sex may also be important. Increasingly, genetics is being considered, and studies are discovering the genetic factors that can influence the development of and survival from sepsis.⁹⁻¹¹ Improved understanding of these aspects should help better direct therapeutic strategies.

I = Infectious Insult

This refers to the specific characteristics of the infection, that is, the agent or pathogen involved (e.g., gram-positive vs. gram-negative, bacteria vs. fungus), the source of sepsis (e.g., urinary tract vs.

respiratory tract), and the degree of extension of the infection (e.g., pneumonia confined to one lobe of one lung vs. generalized bilateral lung involvement, appendicitis vs. generalized peritonitis). All these factors can influence the severity of sepsis response and the patient's likely response to therapy.

R = Host Response

This refers to factors involved in the inflammatory response of the host to the infection and is assessed largely by the presence or absence of the signs and symptoms of sepsis (e.g., degree of elevation of white blood cell count, C-reactive protein [CRP], or procalcitonin). Each patient mounts a different response dependent on various factors including those previously discussed, and a patient's response will vary with his or her clinical course and treatment.

O = Organ Dysfunction

This refers to the degree of organ dysfunction related to sepsis and can be evaluated using various scoring systems, including the SOFA (sequential organ failure assessment) score,¹² which uses objective, readily available measures to quantify the dysfunction of six organ systems (Table 121-1). Dysfunction of each organ is rated according to a scale (0 [normal function] to 4 [organ failure]), and individual scores can then be summed to provide a total. Individual organ function as well as a composite score can thus be followed during the course of the disease and treatment.

CLINICAL PRESENTATION

It has been suggested that sepsis progresses in a continuum through to septic shock, but in the clinical situation, such a progression is not always so clear-cut or constant, and it is difficult to predict which patients are going to develop septic shock and when. Septic shock can develop very abruptly, without evidence of signs of sepsis in the preceding hours.

Septic shock is characterized by the persistence of severe arterial hypotension requiring vasopressor support, despite adequate fluid resuscitation, and the presence of perfusion abnormalities manifest by oliguria, reduced peripheral perfusion, and altered mental status. Septic shock is typically associated with hyperlactatemia (blood lactate concentrations above 2 mEq/L).¹³

One may anticipate that patients with septic shock will have fever, leukocytosis, and other typical features of sepsis, but this is not always true. Fever may be an important clue, but moderate fever can be found in other types of shock. More important, fever is often absent in patients with septic shock; in fact, hypothermia may be present in 10% to 15% of cases, and this feature is associated with higher mortality rates.¹⁴ Tachycardia can be the result of circulatory alterations associated with any type of shock. Leukocytosis is also nonspecific and can be found in other types of circulatory failure; moreover, acute leukopenia may occur in sepsis due to peripheral trapping of activated leukocytes and is also associated with a worse prognosis. Lactic acidosis, a hallmark of all types of circulatory failure, is usually compensated by hyperventilation, so tachypnea is not specific for septic shock.

A more typical characteristic of septic shock is the hyperkinetic pattern characterized by high cardiac output. Although such a hemodynamic pattern is not entirely specific—it can be found in other inflammatory states such as polytrauma or pancreatitis or even anaphylactic shock—it should alert the attending physician to a likely diagnosis of septic shock.

HEMODYNAMIC CHANGES

The inflammatory reaction causes intense vasodilation that increases vascular capacity and results in a fall in arterial blood pressure. Hypovolemia due to fluid loss (e.g., diarrhea, vomiting, or sweating) and alterations in capillary permeability contributes to hypotension, and reduced myocardial contractility can further aggravate the hemodynamic situation, although it is completely reversible when the septic shock resolves. The pathophysiology of reduced myocardial contractility includes alterations in endothelial function, alterations in β -adrenergic receptors, and alterations in myocardial calcium metabolism. These effects are caused largely by sepsis mediators such as TNF- α and IL-1, oxygen free radicals, platelet activating factor, and NO, which all have negative inotropic effects.

After vascular filling as a result of volume resuscitation, the hemodynamic status in septic shock is characterized by a fall in vascular tone associated with reduced systemic vascular resistance and a raised cardiac output. In addition, reduced myocardial contractility causes a fall in the ventricular ejection fraction. Ejection volume and, particularly, cardiac output may be maintained by an increase in diastolic volumes. Hence, there is myocardial depression or dysfunction without

TABLE 121-1 The Sequential Organ Failure Assessment Score

| SOFA SCORE | 0 | 1 | 2 | 3 | 4 |
|--|----------------|-------------------|---------------------------------------|---|--|
| RESPIRATION PaO ₂ /FiO ₂ , mm Hg | >400 | ≤400 | ≤300 | ≤200 with respiratory support | ≤100 with respiratory support |
| COAGULATION Platelets × 10 ³ /mm ³ | >150 | ≤150 | ≤100 | ≤50 | ≤20 |
| LIVER Bilirubin, mg/dL (μmol/L) | <1.2 (<20) | 1.2-1.9 (20-32) | 2.0-5.9 (33-101) | 6.0-11.9 (102-204) | >12.0 (>204) |
| CARDIOVASCULAR Hypotension | No hypotension | MAP < 70 mm Hg | Dopamine ≤5 or dobutamine (any dose)* | Dopamine >5 or epinephrine ≤0.1 or norepinephrine ≤0.1* | Dopamine >15 or epinephrine >0.1 or norepinephrine >0.1* |
| CENTRAL NERVOUS SYSTEM Glasgow Coma Score | 15 | 13-14 | 10-12 | 6-9 | <6 |
| RENAL Creatinine, mg/dL (μmol/L) or urine output | <1.2 (<110) | 1.2-1.9 (110-170) | 2.0-3.4 (171-299) | 3.5-4.9 (300-440) or <500 mL/d | >5.0 (>440) or <200 mL/d |

Data from Vincent JL, de Mendonca A, Cantraine F, et al. Use of the SOFA score to assess the incidence of organ dysfunction/failure in intensive care units. Results of a multicenter, prospective study. Crit Care Med 1998;26:1793-800.

*Adrenergic agents administered for at least 1 hour (doses given are in μg/kg/min).

any true cardiac failure (which would be associated with reduced cardiac output).

MONITORING

Any patient with septic shock requires monitoring with an arterial catheter to enable reliable and continuous assessment of arterial pressure. Changes in systolic and pulse pressures in mechanically ventilated patients during the respiratory cycle may also indicate a greater likelihood of response to a fluid challenge; however, this sign is not reliable when the patient triggers the ventilator.¹⁵ The arterial catheter also facilitates blood sampling, notably for blood gas analysis.

Invasive Versus Less Invasive Monitoring

The role of the pulmonary artery catheter (PAC) in critically ill patients has been questioned. However, although no study has conclusively demonstrated positive effects of this type of monitoring on outcome,¹⁶ information obtained from the PAC may help in guiding patient management in complex cases.¹⁷ The PAC is useful not only for monitoring pulmonary artery occlusion pressure (PAOP) and cardiac output but also for assessment of mixed venous oxygen saturation (SvO_2), a highly useful parameter because a fall in SvO_2 is generally indicative of inadequate oxygen transport.

Less invasive monitoring techniques are increasingly being used. Echocardiography can provide useful additional information, largely to visualize the degree of ventricular filling and ejection volume. However, echocardiography requires an experienced operator, gives no information on the adequacy of cardiac output for the patient's needs, and is difficult to perform continuously, so information is usually intermittent. Other less invasive methods of monitoring cardiac output include PiCCO, LidCO, transesophageal Doppler techniques, and even bioimpedance or bioreactance techniques.¹⁸ However, measurement of cardiac output in isolation is not very helpful in most critically ill patients.

Blood Lactate Levels

The blood lactate level is an important biological variable in determining the adequacy of perfusion and oxygenation. The normal blood lactate level is around 1 mEq/L, and hyperlactatemia becomes clearly pathologic above a level of 2 mEq/L. Although hyperlactatemia is due to cellular hypoxia in other forms of circulatory shock, in septic shock, additional mechanisms may play an important role in raising blood lactate levels. In sepsis, blood lactate levels may be raised by an increase in cellular metabolism, by inhibition of pyruvate dehydrogenase, and by reduced clearance. Repeated measurements enable one to assess the efficacy of treatment¹⁹ and have a predictive value superior to derived oxygenation parameters. The evolution of blood lactate levels enables a global evaluation of the state of shock in response to treatment, although in view of the relatively slow rate of change, blood lactate levels cannot be used to guide resuscitation.

Peripheral Perfusion Parameters

Measurement of the gastric intramucosal pH or its derivatives (mucosal PCO_2 or the difference between the mucosal and arterial PCO_2 [the PCO_2 gap]) is considered to reflect splanchnic perfusion and hence provide an idea of the adequacy of regional oxygenation. However, these techniques may be influenced by technical considerations, including the influence of gastric acid and enteral nutrition, and are not used clinically.

Other techniques for monitoring peripheral perfusion have been developed. While the sublingual region is not a region that would immediately seem to be of most interest, it is easily accessible, and using techniques of orthogonal polarization spectral or sidestream darkfield imaging, heterogeneity of microcirculatory flow and reduced perfused vessel density and proportion of perfused vessels can be

FIGURE 121-1 ■ Representative examples of sublingual microvasculature in a healthy volunteer (*top panel*) and in a patient with septic shock (*lower panel*). Note decrease in density of small vessels in sepsis. (From De Backer D, Creteur J, Preiser JC, et al. Microvascular blood flow is altered in patients with sepsis. *Am J Respir Crit Care Med* 2002;166:98–104, with permission.)

observed (Fig. 121-1) and quantified in patients with sepsis.²⁰ Moreover, the impact of therapeutic interventions on such changes can be monitored,^{21,22} opening the possibility that monitoring the microcirculation could be used to guide treatment.

Near-infrared spectroscopy is a technique that uses the differential absorption properties of oxygenated and deoxygenated hemoglobin to evaluate tissue oxygenation (StO_2). Analysis of changes in StO_2 during a circulatory stress test, such as a brief episode of forearm ischemia (venous or arterial occlusion), may be more useful to quantify sepsis-induced microvascular dysfunction than an isolated StO_2 value.²³

Although these techniques have demonstrated clearly the presence of alterations in the microcirculation in patients with sepsis, which are associated with prognosis,²⁴ further research is needed to fully evaluate the relevance of these values to the early resuscitation and care of critically ill patients.

MANAGEMENT

Septic shock, which systematically causes dysfunction of other organs, is a serious condition, and patients must be stabilized as a matter of urgency. Management of the patient with septic shock involves three inseparable components: treatment of the infection, cardiovascular resuscitation, and modulation of the host response (Fig. 121-2).²⁵

Treatment of Infection

Infection must be treated effectively and rapidly. Antibiotics must be started quickly and must cover all likely organisms.²⁶ The choice of antibiotics may depend on local microbiological flora and resistance

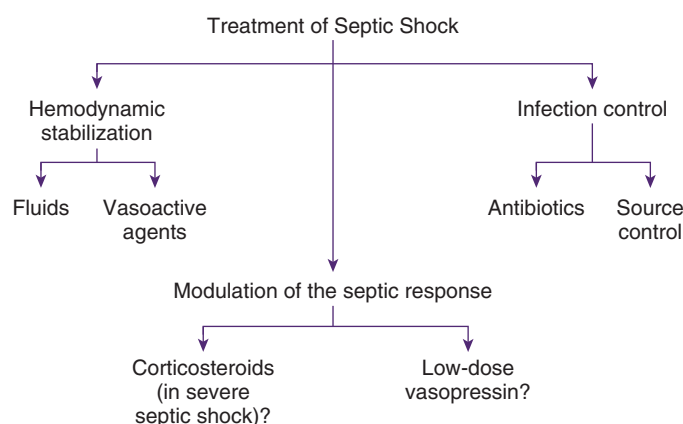

FIGURE 121-2 ■ The three aspects of the treatment of septic shock.

patterns. Often, the microorganism(s) responsible for sepsis in an individual patient is not known for sure, and empiric broad-spectrum antibiotics must be given to ensure adequate coverage. Such empiric therapy must then be modified as soon as microbiology culture results become available.

In addition to antibiotic treatment, any focus of infection must be removed or drained by emergency surgery if necessary. If no source is identified, a systematic search should be made based on the “big five”: lungs, abdomen, urine, wounds, and catheters.

Cardiovascular Resuscitation

The VIP rule proposed by Weil and Shubin²⁷ should be followed. Each patient is in fact a VIP, but the letters refer here to *Ventilation, Infusion, and Pump*.

V = Ventilation

All patients with septic shock must be generously oxygenated with the aim of correcting any hypoxemia, regardless of whether it is due to inadequate cardiac output, pulmonary edema, or pulmonary disease. Severe cases need endotracheal intubation and mechanical ventilation. Noninvasive ventilation is not recommended in such hemodynamically unstable patients. Even though it may represent a temporary support rather than a treatment per se, mechanical ventilation allows not only an improvement in gaseous exchange but also has beneficial hemodynamic effects, notably by reducing the oxygen requirement of the respiratory muscles.

I = Infusion

Septic shock is accompanied by absolute and relative hypovolemia, the result of various mechanisms:

- External losses, which may be obvious, such as vomiting and diarrhea, or less apparent, such as sweating
- Internal losses via an increase in capillary permeability with development of edema and sometimes liquid effusions (peritoneal, pleural effusion)
- Increase in plasma volume associated with arterial and venous dilatation

Hypovolemia needs to be corrected rapidly as it causes hemodynamic instability both at the level of cardiac output and in terms of peripheral perfusion.

Assessment of an adequate volume state is essentially clinical: restoration of arterial pressure, improvement of cutaneous perfusion, improved urine output, and improved mental state. The central venous pressure (CVP) can be a useful guide, but it is not possible to define in advance the CVP that should be reached in any individual patient. Measurements of CVP or PAOP are primarily used as a limit

TABLE 121-2

The Fluid Challenge Technique (with the TROL Mnemonic)

| DEFINE | EXAMPLE |
|------------------|----------------------------------|
| Type of fluid | Ringer's lactate |
| Rate of infusion | 200 mL in 10 min |
| Objective | Mean arterial pressure >75 mm Hg |
| Limits | Central venous pressure 16 mm Hg |

to fluid administration in order to minimize the risk of pulmonary edema. In fluid replacement, it is preferable to use a fluid challenge technique, in which filling pressures are measured at regular intervals during fluid administration (Table 121-2).²⁸ If cardiac output is monitored, one should ensure that it increases with fluid boluses, and such fluid administration should be stopped when cardiac output reaches a plateau.

There has been considerable debate as to which fluid should be used in sepsis, but it is the quantity of fluid rather than the type of fluid per se that is of greatest importance. Because of their propensity for leakage into the extravascular space, greater volumes of crystalloids are needed to achieve the same effect as colloids,²⁹ thus potentially increasing the risk of edema, but colloids are more expensive and carry their own risks. In particular, there has been considerable controversy about the use of albumin in critically ill patients, but the SAFE study suggested a decrease in mortality associated with albumin administration in patients with sepsis.³⁰ Most clinicians would use some albumin in septic patients with significant hypoalbuminemia.

P = Pump (Vasoactive Agents)

If fluid administration alone is unable to restore an adequate perfusion pressure, vasoactive agents are required. Catecholamines are preferred for their rapid action and efficacy and their short half-lives. Adrenergic agents stimulate β_1 - (positive inotropes), β_2 - (essentially vasodilators and bronchodilators), and α - (essentially vasoconstrictors) receptors to varying degrees. Dopamine also stimulates dopaminergic receptors, causing vasodilation primarily in the splanchnic and renal regions, but the clinical relevance of this effect is doubtful.

A randomized controlled study showed that dopamine use is associated with increased adverse effects, notably arrhythmias, in patients with shock,³¹ and a meta-analysis indicated that dopamine administration is associated with higher mortality rates than norepinephrine in septic shock.³² Norepinephrine is, therefore, the preferred first-line vasopressor in patients with septic shock. Epinephrine should not be used as a first-line vasopressor in patients with septic shock; it can have deleterious effects on splanchnic circulation and increase cellular metabolism. Dobutamine is often added to vasopressor therapy, particularly when using norepinephrine, to increase cardiac output by its positive inotropic effects.

The place of vasopressin derivatives is not well defined. Patients with septic shock usually have a degree of relative vasopressin deficiency so that vasopressin supplementation may be warranted. Recent studies have suggested that vasopressin is involved in endothelial protection so that early administration of vasopressin derivatives may limit edema formation.³³ This hypothesis is presently being tested in clinical trials.

Immunomodulation

Clinical trials assessing drugs that limit the effects of proinflammatory cytokines such as TNF- α (anti-TNF antibodies, TNF receptors) and IL-1 (IL-1 receptor antagonist inhibitors) have not given convincing results on beneficial effects of these agents on outcome, probably largely because such cytokines have multiple effects, beneficial as well as harmful. Administration of activated protein C (drotrecogin alfa [activated]) early in septic shock reduced mortality and morbidity in

initial studies,³⁴ but the drug was withdrawn from the market after a later negative placebo-controlled study.³⁵

The administration of large doses of corticosteroids for patients with septic shock was proposed many years ago. More recently, the concept of relative adrenal insufficiency has emerged, and administration of moderate doses of corticosteroids (200 mg hydrocortisone in 24 hours) in patients with septic shock has been proposed, but this is also debated.^{36,37}

The treatment of fever is controversial. Increased body temperature increases oxygen requirements, but the increased cellular metabolism may form part of the body's natural defense. Animal studies have suggested that control of fever is detrimental³⁸ and that the release of heat shock proteins in fever may have important protective effects.³⁹ A multicenter study of acetaminophen in febrile ICU patients with suspected infection showed that the drug was well tolerated but did not reduce mortality.⁴⁰

High-flow hemofiltration techniques can remove a range of bacterial products and mediators but are not without risk, notably because this process can remove beneficial products such as hormones and medications, including antibiotics, as well as potentially harmful substances.⁴¹ Clinical studies have provided conflicting data regarding the effects of these techniques on outcomes.⁴²

Nutritional Support

Malnutrition can prolong the course of sepsis and increase the risk of complications. When considering nutritional support in patients with septic shock, several factors should be remembered:

- There is no urgency to start nutritional support, unless the patient is malnourished.
- The enteral route is preferable to the parenteral route.
- Enteral nutrition should not be started during the initial phase of resuscitation. Although studies are limited, increasing the oxygen requirements of the gut is probably unwise in circulatory shock. However, as soon as the patient has achieved a degree of hemodynamic stability (after a maximum of 24–48 hours), enteral nutrition should be started.
- There is no urgency to start parenteral nutrition. Waiting a few days is acceptable.
- Careful control of blood glucose levels is recommended. Control of blood glucose levels has been shown to be associated with improved outcomes,⁴³ but hypoglycemia can be a problem with very strict blood glucose protocols. A suggested target glucose concentration is, therefore, 110 to 150 mg/dL.^{25,44} Variability in glucose levels should also be avoided.⁴⁵

Organ Support

Organ dysfunction can involve any organ and can be quantified using the SOFA score (see Table 121-1). Techniques for individual organ support are covered in separate chapters, but an overview is given here.

Respiratory Alterations

Respiratory failure is a common complication of sepsis and is usually characterized by hypoxemia. The diagnosis of acute respiratory distress syndrome is made when the $\text{PaO}_2/\text{FiO}_2$ ratio is less than 300 mm Hg in the presence of bilateral infiltrates on a chest radiograph, with no evidence of left heart failure.⁴⁶

When starting a patient on mechanical ventilation, several factors need particular attention:

- Worsening of arterial hypotension when starting mechanical ventilation suggests the presence of hypovolemia due to a reduction in venous return (and hence in cardiac output) when intrathoracic pressures are increased.

- Tidal volume should be limited, not only for hemodynamic reasons but also to avoid a major inflammatory reaction.
- Sedation must be avoided whenever possible. Administration of sedative drugs and analgesics should be titrated with respect to the needs of the individual patient. Reduced administration of sedative agents can shorten the duration of mechanical ventilation and ICU stay.^{47,48}

Renal Alterations

Sepsis is the leading cause of acute renal failure in the ICU.⁴⁹ Renal function can worsen as a result of combined circulatory changes and inflammation. In addition, management of septic patients often involves administration of nephrotoxic agents—for example, aminoglycosides or contrast material for radiologic examinations.

Unfortunately, there is no prophylactic approach to renal failure other than to try to maintain adequate renal perfusion and overall volume state. Administration of low (renal)-dose dopamine is ineffective at preventing renal failure,⁵⁰ and diuretics may be harmful.⁵¹

Renal replacement therapy is frequently necessary in septic patients. In septic shock, continuous venovenous techniques, with or without dialysis, are generally preferred over intermittent techniques to facilitate control of fluid balance.

Coagulation Alterations

Coagulopathy is common in septic shock. A low platelet count is common and may be associated with a prolonged prothrombin time and an activated partial thromboplastin time. Treatment of these alterations revolves primarily around the cause, and there is no indication for heparin therapy. In severe cases associated with significant bleeding, administration of fresh frozen plasma or platelet infusions may be indicated.

Hepatic Alterations

Circulatory shock of any cause frequently results in the elevation of liver-associated enzyme levels, but the contribution of various organs (e.g., muscles) to increased enzyme levels is difficult to quantify. Often there is a rise in bilirubin levels after several days, without evidence of hemolysis, major hematomas, or biliary pathology. Supplementary examinations such as ultrasound may be indicated to exclude any associated biliary pathology.

Cerebral Function Alterations

Circulatory shock is typically accompanied by an alteration in intellectual function, initially manifested as confusion without real coma. Cerebral alterations can be prolonged, and the patient is then said to have septic encephalopathy. The exact cause of the encephalopathy is unclear, although various mediators of sepsis have been implicated. Investigations are of little use except to exclude other causes. The electroencephalogram generally shows a slow diffuse slowing,⁵² whereas cerebral computed tomography and cerebrospinal fluid examination are normal. These alterations are usually fully reversible with the resolution of shock.

CONCLUSION

Optimal treatment of a patient with septic shock requires a rapid and effective management plan with the assistance of the full ICU team. Infection control and achieving hemodynamic stability must be tackled simultaneously. Other interventions are currently undergoing clinical trials, with the hope that they will improve the microcirculatory changes of sepsis or beneficially modulate the host response. A better characterization of patients with septic shock—for example, by using the PIRO system—is necessary to appropriately titrate therapeutic interventions to individual patients.

KEY POINTS

1. Septic shock affects about 15% of ICU patients and has a mortality rate of close to 50%.
2. Septic shock is most commonly caused by a bacterial infection, although fungi, viruses, and parasites can all be implicated. The most common source of infection is the lung, followed by the abdomen.
3. Patients with sepsis can be classified according to their predisposing factors, the nature of the infection, degree of immune response, and associated organ dysfunction.
4. *Septic shock* is defined as sepsis with organ dysfunction with persistent arterial hypotension requiring vasopressor administration despite adequate fluid resuscitation, in the presence of perfusion abnormalities manifested by oliguria, reduced peripheral perfusion, and/or altered mental status.
5. Blood lactate levels are typically raised in septic shock, and persistently raised levels are a poor prognostic sign.
6. Management of septic shock includes infection control, hemodynamic stabilization, and modulation of the host response.

CHANGING OUTCOMES AND EPIDEMIOLOGY

The mortality rate due to neonatal and pediatric severe sepsis has improved from 97% in 1963 to 9% in 1999 to 4% in 2003.¹⁻⁴ Previously healthy children have better outcomes than children with chronic illness. The randomized controlled trial of bactericidal permeability-increasing protein⁵ for children with purpura fulminans/presumed meningococcal septic shock showed 10% mortality rates in the placebo groups. The reported outcomes in children with septic shock when using therapeutic approaches similar to those recommended in the 2002 American College of Critical Care Medicine *Clinical Practice Parameters for Hemodynamic Support of Pediatric and Neonatal Patients in Septic Shock*⁶ show a decreasing tendency. In children with meningococcal septic shock in the United Kingdom, a 5% mortality rate was reported,⁷ and in the Netherlands, a decreasing mortality was shown in the same patient group.⁸ Ngo and colleagues⁹ observed a 0% mortality rate in a randomized dengue shock fluid resuscitation trial. The U.S. KIDS database showed an overall 4.2% severe sepsis mortality, with 2% in previously healthy and 8% in chronically ill children.³ The most recent implementation of the AAP-CHA septic shock initiative in 22 pediatric emergency departments showed a reduction in hospital mortality from 11% to 3%, with the use of an identification trigger tool and administration of fluids and antibiotics within the first hour of presentation.¹⁰ This timely administration of antibiotics and fluids also decreases the incidence of organ dysfunction and multiple organ failure.¹¹

Although outcomes are improving, the burden of newborn and pediatric sepsis is increasing in the United States. More children die with severe sepsis than with cancer, with an estimated yearly healthcare cost of \$4 billion in the United States for patients with this condition.⁴ Half are newborns, with most of these having a low birth weight. Half of the children with severe sepsis have underlying chronic illness. Neurologic and cardiovascular chronic illnesses are most common in infants with severe sepsis and cancer, whereas immune deficiency is most common in children with severe sepsis. Medical advances have affected etiology and epidemiology. In 1990, Jacobs and coworkers¹² reported that the most common causes of septic shock in children were, in descending order, *Haemophilus influenzae* b, *Neisseria meningitidis*, and *Streptococcus pneumoniae*. The 1995 and 1999 U.S. estimates suggest a change. *H. influenzae* type b is all but nonexistent; *N. meningitidis* is prevalent in only a few regions of the United States, and group B *Streptococcus* is decreasing. The more recent use of the *S. pneumoniae* vaccine is reducing the incidence of this infection. The Canadian government has implemented nationwide immunization in children younger than 2 years for *N. meningitidis* serotype C.¹³ The most prevalent causes of severe sepsis and septic shock in the United States now seem to be staphylococcal and fungal infections.⁴ Methicillin-resistant *Staphylococcus aureus* (MRSA) is an emerging disease.¹⁴ Influenza vaccines are now universal for both endemic and pandemic forms (H1N1). While mortality rates in the United States are decreasing in all other organisms, they are doubling in children with *S. aureus* infection, underlining the need for first-line MRSA coverage in children with severe sepsis.^{4,14}

PATHOPHYSIOLOGY AND DEVELOPMENTAL EFFECTS

Molecular Pathogenesis

Controlled Inflammation with Eradication of Infection

Endotoxin, mannose, and other glycoprotein moieties on the cell walls of yeast and fungi, superantigens, toxins associated with some gram-positive bacteria, mycobacteria, and viruses, also called *pathogen-associated molecular patterns*, activate the innate immune system after recognition by pathogen recognition receptors. The innate immune system comprises polymorphonuclear neutrophils, monocytes, and macrophages, in part through Toll-like receptors, CD14 receptors (endotoxin), and other costimulatory molecules. These innate immune cells internalize microorganisms and kill them. Monocytes and macrophages present processed antigens from these killed microorganisms to circulating T lymphocytes and coordinate the adaptive immune response. This second wave of immune response includes B-cell activation and antibody production and generation of cytotoxic T cells and natural killer (NK) cells (particularly in viral and fungal infection). Opsonization with antibodies allows the more efficient recognition, killing, and clearing of microorganisms by resident macrophages in the reticuloendothelial system.^{15,16}

The activated inflammatory cells also initiate a series of biochemical cascades that result in phospholipase A₂, platelet-activating factor, cyclooxygenase, complement, and cytokine release that orchestrate an efficient and controlled inflammatory/immune response. The cytokines tumor necrosis factor (TNF) and interleukin (IL)-1 β synergistically interact to promote positive feedback cascades that result in fever and vasodilation. These cytokines stimulate the production of many important effector molecules, including proinflammatory cytokines (e.g., IL-6, IL-8, and interferon [IFN]-gamma), which promote immune cell-mediated killing and antiinflammatory cytokines (e.g., soluble TNF receptor, IL-1 receptor antagonist protein, IL-4, and IL-10), which turn off the immune response when the infection has been cleared. These cytokines stimulate nitric oxide (NO) production, which leads to vasodilation. NO combines with superoxide radicals to form peroxynitrite radicals (ONOO⁻), which participate in the intracellular killing of microorganisms. Cytokines increase the expression of endothelial-derived adhesion molecules, including E-selectin, which facilitates white blood cell rolling, and intercellular adhesion molecule and vascular adhesion molecule, which facilitate white blood cell adhesion and diapedesis. This activity guides activated inflammatory cells to the site of infection. The cytokines induce a change in the endothelium to a prothrombotic and antifibrinolytic state. Expression of thrombomodulin is possibly decreased, and expression of the prothrombotic molecule tissue factor and the antifibrinolytic molecule plasminogen activator inhibitor-1 (PAI-1) is increased. The ensuing thrombus "walls off" the infection and allows vascular remodeling until antiinflammatory cytokines turn off the proinflammatory cytokine response and restore the antithrombotic profibrinolytic milieu after the infection is cleared.

Uncontrolled Inflammation and Persistent Infection Lead to Septic Shock and Multiple Organ Failure

If the controlled activated immune cell response is ineffective in killing the infectious agent and clearing the antigen or if inflammation is uncontrolled, systemic organ injury ensues. Increased TNF and NO production in cardiac cells and circulating myocardial depressant substances can lead to cardiac dysfunction and cardiovascular collapse. Peroxynitrite can cause DNA damage, and subsequent polyadenosyl ribose synthase activation depletes cells of oxidized nicotinamide adenine dinucleotide and adenosine triphosphate (ATP), leading to secondary energy failure. Thrombosis and antifibrinolysis become systemic. Antithrombotic molecules, including protein C and antithrombin III, are consumed, and ongoing systemic release of tissue factor and PAI-1 results in unremitting thrombosis. At some point, the consumption of procoagulant factors leads to a precarious state in which thrombosis is accompanied by bleeding because there are insufficient clotting factors. The antiinflammatory response becomes deleterious. IL-10 induces a T_H2 response and reduces the ability of monocytes/macrophages to kill the infection. Overactivated immune cells release Fas and Fas ligand. Circulating Fas prevents activated immune cell apoptosis and ensures ongoing inflammation, and the Fas ligand can induce liver injury. In patients with NK cell dysfunction, activated immune cell death is further hampered. Ineffective and unresolving inflammation leads to systemic organ failure.

Clinical Pathologic Correlates

On the basis of in vivo biochemical analyses and an autopsy histology, several forms of multiple organ failure could be characterized.¹⁷⁻²⁷ *Thrombocytopenia-associated multiple organ failure* (platelet count < 100,000/ μ L or a 50% decrease in platelet count from baseline) was attributable to purpura fulminans and disseminated intravascular coagulation (DIC) with increased tissue factor activity in vivo and fibrin thrombi at autopsy in only 20% of patients. Of these patients, 80% showed thrombotic thrombocytopenic purpura pathophysiology with increased thrombogenic ultralarge von Willebrand factor (vWF) multimers, absent vWF cleaving protease (ADAMTS 13), increased PAI-1 activity in vivo, and platelet/fibrin thrombi at autopsy. This phenotype responds well to daily plasma exchange, which removes ultralarge vWF multimers and restores ADAMTS13 activity.²¹ The monoclonal C5A antibody eculizumab is FDA approved for children with this syndrome and atypical TTP-HUS.²²

Sequential or liver dysfunction-associated multiple organ failure (shock/acute respiratory distress syndrome followed sequentially by liver and renal failure) was associated with viral sepsis and lymphoproliferative disease.²³ Patients were found to have unremitting Epstein-Barr virus (EBV) infection, with lymphocyte Fas ligand-mediated destruction of liver and high circulating Fas and Fas ligand levels. This syndrome is also found in patients with defects in NK cell activity. Absent NK cell activity is found in primary hemophagocytic lymphohistiocytosis (HLH), and decreased NK cell activity is found in secondary HLH. NK cells are responsible for killing viruses and stopping lymphoproliferation. Posttransplant-related lymphoproliferative disease is treated with the CD20 monoclonal antibody rituximab, which eradicates the EBV reservoir.²⁴

Unresolving multiple organ failure with prolonged monocyte deactivation (monocyte HLA-DR expression <30% or ex vivo TNF response to lipopolysaccharide <200 pg/mL for >5 days) was associated with secondary bacterial, fungal, or herpesvirus family infection. These patients had elevated IL-10 and IL-6 levels. Patients who died had infection at autopsy.²⁵ This was associated with *lymphoid depletion syndrome* (lymphocyte depletion of the lymph nodes and spleen) at autopsy.²⁶ All these children had fungal, bacterial, or herpesvirus family infection at the time of death. Risk factors (odds ratio >10) for this process included lymphocytopenia (<1000/ mm^3) or hypoprolactinemia or both for more than 7 days. Phagocytosis of these apoptotic bodies by monocytes/macrophages leads to immunoparalysis. Daily

GM-CSF can reverse this process and prevent secondary infections.²⁵

Sepsis with features of *macrophage activation syndrome* is defined clinically by the presence of DIC, and hepatobiliary dysfunction with hyperferritinemia (>500 ng/mL) can be a manifestation of macrophage-driven hyperinflammation related to uncontrolled inflammation secondary to an uneradicated source or to an inflammation phenotype left untreated. Histology shows hemophagocytic histiocytosis in the presence or absence of increased CD8 T cells and reduced NK cells. Treatment of this syndrome with IL1RAP was associated with a reduction in mortality from 60% to 31% in adult patients with severe sepsis.²⁷

These clinical pathologic correlates support the following hypotheses: (1) uncontrolled inflammation contributes to organ failure after septic shock, (2) uncontrolled inflammation contributes to systemic thrombosis, (3) uncontrolled inflammation leads to adrenal dysfunction not only through thrombosis but also potentially through NO-mediated inhibition of cytochrome P450 activity, (4) uncontrolled inflammation is commonly associated with uneradicated infection, and (5) it is likely that genetic and environmental factors increase a patient's risk of systemic thrombosis and uneradicated infection and the development of inflammation phenotypes that can respond to personalized therapies.

Coagulation System

As is generally accepted and explained in many reviews, coagulation and fibrinolysis are integral parts of the immune system.²⁸ There are important physiologic differences in the hemostatic system in children compared with adults. The decreased levels of several crucial coagulants and increased levels of α_2 -macroglobulin may contribute, in part, to the lower risk of thrombotic events in childhood during physiologic conditions.^{29,30} In pathologic conditions, these physiologic differences might lead to an earlier exhaustion of coagulation factors and DIC in infants and young children.³¹ ADAMTS 13 is decreased in infancy; therefore, there may be an increased susceptibility to systemic fibrin and platelet thrombosis. The coagulation system is a marker of organ dysfunction in sepsis. It is associated with subsequent endothelium activation and systemic clotting and finally antifibrinolysis.

Cardiovascular System

Ceneviva and associates³² found that in contrast to adults, who predominantly have high cardiac output/low vascular resistance shock, children with fluid-refractory/inotropic-resistant shock have varied hemodynamic states, including low cardiac output/high systemic vascular resistance (60%), low cardiac output/low vascular resistance (20%), and high cardiac output/low vascular resistance (20%), which can change with time and depend on age. In contrast to adults, death from shock is most commonly associated with progressive cardiac failure, not vascular failure. Infants and children are frequently insensitive to dopamine or dobutamine and respond to epinephrine (cold shock) or norepinephrine (warm shock).³²⁻³⁴ Newborns are different as well. Adults can double their heart rate to improve cardiac output, but newborns cannot. Newborns, although tachycardic, depend on increased vascular tone to maintain blood pressure. Persistent pulmonary hypertension and right ventricular failure complicate newborn septic shock.^{35,36}

PREDISPOSING FACTORS AND PREVENTION STRATEGIES

Environmental and genetic factors associated with reduced immune function predispose children to the development of sepsis and septic shock. These factors include age (prematurity, neonate, and age <1 year), cancer and immunosuppressive chemotherapeutic agents, transplantation and immunosuppressive agents, primary immunodeficiency disorders (e.g., hypocomplementemia, hypogammaglobulinemia, or chronic granulomatous disease), acquired immunodeficiency

disorders (neutropenia, lymphocytopenia, or monocyte deactivation), and malnutrition. Prolonged use of invasive catheters, muscle relaxants, and broad-spectrum antibiotics also predisposes to infection.

Among the community-acquired causes of sepsis, *N. meningitidis* has a diverse clinical picture, ranging from a self-limiting bacteremia to meningitis to a severe rapidly fatal sepsis. After invasion of the bloodstream by the bacteria, three main cascade pathways are activated: the complement system, the inflammatory response, and the coagulation and fibrinolysis pathway. These pathways do not act independently but are able to interact with each other. Genetic polymorphisms among components of these pathways have been shown to be involved in the susceptibility, severity, and outcome of meningococcal disease. Knowledge of genetic variations associated with susceptibility to and severity of meningococcal infection has been reviewed.³⁷

Complement deficiencies and defects in sensing or opsonophagocytic pathways, such as the rare Toll-like receptor 4 single nucleotide polymorphisms and combinations of inefficient variants of Fcγ-receptors, seem to have the most important role in genetically established susceptibility. The most recent and largest study on susceptibility is a genome-wide analysis of DNA from 1600 children with meningococcal sepsis. The results of this study showed the significant influence of genetic variants in the complement factor H in the susceptibility.³⁸ This deficiency has been associated with atypical TTP-HUS, which manifests as *thrombocytopenia-associated MOF*. Plasma exchange and the C5a monoclonal antibody eculizumab have been used to treat these children and adults.²⁷ The effect on severity has repeatedly been reported for FcγRIIa and PAI-1 polymorphisms. Angiotensin-converting enzyme is associated with a proinflammatory response. The absence of a 284-base pair marker in the angiotensin-converting enzyme gene (D allele) is associated with higher circulating angiotensin-converting enzyme activity than the presence of an I allele. The DD genotype is associated with increased disease severity, and although not significant, a twofold increase in mortality rate has been reported. Outcome effects have been confirmed for single nucleotide polymorphisms in properdin deficiencies, PAI-1 and combination of the -511C/T single nucleotide polymorphisms in IL-1β, and +2018C/T single nucleotide polymorphisms in IL RN. Conflicting results are reported for the effect of the -308G/A promoter polymorphism in TNF. These differences may reflect discrepancies in group definitions among studies or the influence of additional single nucleotide polymorphisms in the TNF promoter, which can form haplotypes representing different cytokine production capacity. For several single nucleotide polymorphisms, the potential effect on susceptibility, severity, or outcome has not yet been confirmed in an independent study.

The hallmark of pediatric medicine is prevention. Public health programs that reduce prematurity could be expected to have the greatest impact on the incidence of sepsis. The use of group B streptococcal prophylaxis in at-risk mothers has reduced the incidence of septic shock in premature and term infants. Immunization programs for diphtheria, pertussis, tetanus, measles, mumps, rubella, *H. influenzae* type b, *S. pneumoniae*, *N. meningitidis* (type C for infants and types C, A, and Y for college students), and influenza effectively reduce the incidence of sepsis in newborns and children. The primary immunodeficiency initiative is an important physician education program. Children with frequent pneumonia, sinus infections, or skin infections can benefit from early immunodeficiency workups, including quantitative immunoglobulins, complement levels, nitroblue toluene testing of polymorphonuclear neutrophil function, and antibody titer response to immunization. Early identification of these children can lead to the use of therapies that reduce the incidence of sepsis.

DIAGNOSTIC APPROACH AND SCORING SYSTEMS

The following prognostic factors are related to severity and nonsurvival:

- Increased levels of endotoxin, cytokines, lactate, PAI-1, adhesion molecules, procalcitonin, elastase, troponin, adrenocorticotrophic hormone, and ferritin.³⁹
- Decreased levels of C-reactive protein (or increased), glucose, fibrinogen, coagulation factors, protein C, ADAMTS 13, leukocytes, and platelets
- Many scoring systems in use are specific for pediatric patients, including pediatric risk of mortality⁴⁰ and pediatric organ failure and are specific for certain categories of patients, including Rotterdam score,⁴¹ Glasgow Meningococcal Septicaemia Prognostic Score,⁴² DIC,^{43,44} PELOD,⁴⁵ and adapted adult scores (e.g., organ failure score).⁴⁶

THERAPY

Early Recognition and Goal-Directed Therapy to Improve Outcome

Early recognition, adequate resuscitation, appropriate therapeutic response, removal of the nidus of infection, and effective antibiotic therapy are crucial to optimal outcome.⁴⁷ In June 2007, the American College of Critical Care Medicine published its evidence-based *Clinical Practice Parameters for Hemodynamic Support of Newborns and Children with Septic Shock* based, in part, on the concept that early recognition and resuscitation improve outcome (Fig. 122-1). The major new recommendations include the use of epinephrine through a peripheral intravenous (IV) or intraosseous catheter until a central catheter is available and administration of antibiotics in the first hour.⁴⁸

Immediate Resuscitation (First Hour)

Airway and Breathing

Newborns and children usually have an adequate airway, but mechanical ventilation is required in 80% in shock. Intubation should be performed according to pediatric advanced life support and Neonatal Resuscitation Program guidelines on the basis of clinical diagnosis of respiratory distress or hemodynamic instability, not blood gas analysis. Volume resuscitation and the use of the noncardiac depressant drug ketamine as an induction agent are recommended to prevent worsening positive-pressure ventilation-associated hypotension. It is clinical practice to intubate pediatric patients in an early stage of the disease, generally when they need more than 60 mL/kg of fluid resuscitation.

Volume Resuscitation

Virtually all children with shock require volume resuscitation^{49,50}; this should be given as 20-mL/kg boluses of normal saline or colloid as IV pushes to as much as 40 to 60 mL/kg in the first 10 to 20 minutes. If the liver edge becomes palpable, rales are heard, or the perfusion pressure (mean arterial pressure – central venous pressure) narrows, more fluid is not advised and diuretics should be considered. Many clinicians use crystalloid as the first fluid and follow with colloid when more fluids are required. Serum glucose levels should be checked because hypoglycemia can have devastating neurologic consequences. Glucose should be administered rapidly in this condition.

Cardiovascular Therapy

Children in shock can present with low cardiac output and high systemic vascular resistance, high cardiac output and low systemic vascular resistance, or low cardiac output and low systemic vascular resistance. Depending on which situation exists, inotropic support should be started in case of fluid-refractory shock or a combination of an inotrope with a vasopressor or vasodilator. Peripheral epinephrine is probably the first choice of support for a pediatric patient with hypotension refractory to fluid resuscitation until central access can be attained. Dobutamine-refractory or dopamine-refractory shock can often be reversed with epinephrine or norepinephrine infusion. Pediatric patients requiring inotropic support are in a state of low cardiac output,

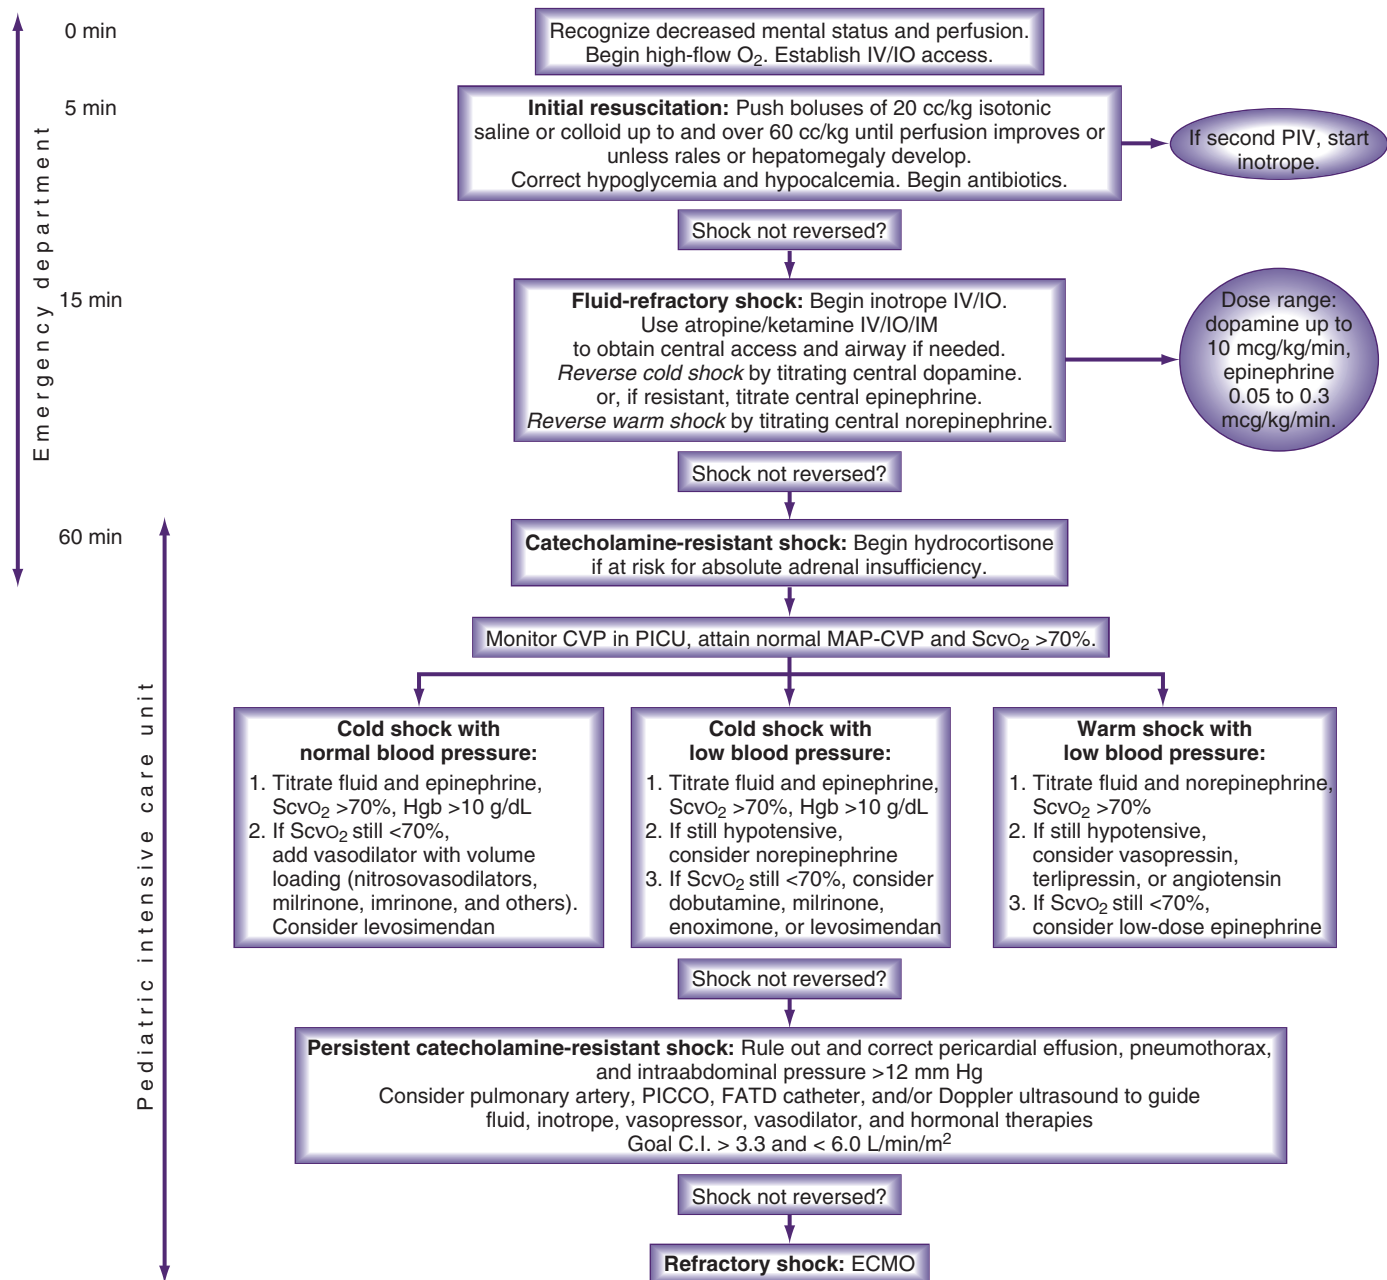

FIGURE 122-1 ■ Clinical practice parameters for hemodynamic support of newborns and children with septic shock. This evidence-based treatment algorithm is based on early recognition and resuscitation to improve outcome. ACTH, adrenocorticotropic hormone; APLS/PALS, advanced pediatric life support/pediatric advanced life support; CI, cardiac index; CVP, central venous pressure; ECMO, extracorporeal membrane oxygenation; FATD, femoral artery thermodilution; MAP, mean arterial pressure; PDE, phosphodiesterase; PICCO, pulse index contour cardiac output; PICU, pediatric intensive care unit; ScvO₂, central venous oxygen saturation. (From Brierly J, Carcillo JA, Choong J, et al. Clinical practice parameters for hemodynamic support of pediatric and neonatal septic shock: 2007 update from the American College of Critical Care Medicine. Crit Care Med 2009;37: 666–688.)

not high cardiac output. The use of vasodilators can reverse shock in pediatric patients who remain hypodynamic with a high systemic vascular resistance state, despite fluid resuscitation and inotropic support implementation. Milrinone or nitrovasodilators (nitroprusside or nitroglycerin have a short half-life) are used as first-line therapy for children with epinephrine-resistant low cardiac output and elevated systemic vascular resistance shock.

Adrenal Insufficiency

Lack of response to epinephrine (cold shock) or norepinephrine (warm shock) can be caused by adrenal insufficiency or thyroid deficiency.⁵¹⁻⁵³ Children at risk of this condition (e.g., purpura fulminans, prior steroid exposure, or central nervous system disease) should be treated with hydrocortisone. The proper dose has been poorly investigated and

ranges from a stress dose (2 mg/kg) to a shock dose (50 mg/kg of hydrocortisone), followed by the same dose over 24 hours as a continuous infusion. The dose that is better in catecholamine-resistant shock has not been determined.

Antibiotics

Antibiotics and antifungal therapies should be administered according to age, setting, and resistance patterns (empiric therapy) after proper cultures have been performed. The emergence of resistant organisms mandates that antibiotics be specific to regional practice. Some investigators advocate antibiotic cycling in the ICU.⁵⁴

Stabilization of Sepsis and Septic Shock (After First Hour of Resuscitation)

Cardiovascular

The first hour of resuscitation is directed toward restoration of normal perfusion pressure; however, ensuing therapies should be directed toward obtaining normal central venous oxygen saturation. Children with persistent warm shock can respond to norepinephrine. In selected children with norepinephrine-resistant shock, vasopressin (at a physiologic dose) or angiotensin can bypass alpha receptor desensitization and restore vascular tone; however, this can increase afterload and decrease cardiac output.⁵⁵⁻⁵⁷ In a large study in pediatric patients with vasodilatory shock (majority being post cardiac surgery), vasopressin was useful, with limitations regarding its adverse effects on the renal system and platelet counts.⁵⁸ Children with cold shock and normal blood pressure respond to afterload reduction and volume loading. When pediatric patients remain in a normotensive low-cardiac output and high-vascular resistance state despite epinephrine and nitrovasodilator therapy, the use of milrinone should be strongly considered.⁵⁹ This type III phosphodiesterase inhibitor can bypass β -adrenergic receptor desensitization.⁵⁹⁻⁶¹ Children with cold shock and hypotension are most worrisome. They can respond to more volume and epinephrine. Neonates and children with pulmonary hypertension and right ventricular failure can respond to inhaled NO.⁶² These therapies should be titrated to obtain a superior vena cava oxygen saturation above 70%.⁶³

Extracorporeal membrane oxygenation (ECMO) is an effective therapy in refractory neonatal shock (80% survival) and should be considered as a possible therapy in refractory pediatric shock (50% survival).^{64,65} This success is likely due to the fact that refractory shock in newborns and children is usually cardiac, not vascular, failure. Adults with refractory shock from *Hantavirus* (a low-cardiac output/high-vascular resistance state) have similar ECMO outcomes to newborns with refractory shock.⁶⁶

Respiratory

Lung “protection” ventilation strategies reduced mortality rates in adults with acute respiratory distress syndrome (many who had sepsis).⁶⁷ Effective tidal volumes of 6 mL/kg are a reasonable compromise when ventilating septic children with acute respiratory distress syndrome. Positive end-expiratory pressure protects against volutrauma by maintaining functional residual capacity and optimal compliance. Optimal positive end-expiratory pressure can be determined using partial pressure of oxygen in the arterial blood-to-inspired oxygen fraction ratio or compliance.

Renal Failure

Renal failure occurs if ischemia continues for longer than 60 minutes, thrombosis prevents perfusion, or myoglobin and uric acid obstruct tubular flow. During the first 60 minutes of ischemia, the neurohormonal system releases aldosterone, angiotensin, and the antidiuretic hormone (vasopressin), which prevent natriuresis and diuresis; this manifests clinically with oliguria. Rapid resuscitation reverses ischemia, and because 20% of the blood flow goes to renal perfusion, it manifests as return of urine output greater than 1 mL/kg/h. If ischemia lasts more than 1 hour, ATP depletion causes epithelial cells to separate

from and obstruct tubules, leading to tubulobstructive renal failure (also called *acute tubular necrosis*). Tubular regeneration requires 6 weeks to 3 months.

Blood flow to the kidney is autoregulated by pre- and postglomerular constriction and dilation. The ability of the preglomerular arterioles to dilate is impaired during endotoxemia and cirrhosis. Blood flow to the kidney depends on perfusion pressure (measured as mean arterial pressure – central venous pressure or, in the case of abdominal compartment syndrome, mean arterial pressure – intraabdominal pressure) in children with sepsis.⁶⁸ Perfusion pressure should be maintained with volume, inotropes, and in some cases, vasopressor therapies. Creatinine clearance should be measured daily to assess function. Diuretics are recommended to prevent fluid overload. Patients with myoglobinuria or uric aciduria should be treated with mannitol, alkalization, and allopurinol (uric aciduria). Severe oliguria or anuria, despite the use of diuretics, should be managed with daily or continuous hemofiltration/hemodialysis or peritoneal dialysis.

Purpura Fulminans and Disseminated Intravascular Coagulation

DIC is recognized clinically as a prolonged prothrombin time/partial thromboplastin time, reduced fibrinogen, increased fibrin degradation products or D-dimers, and thrombocytopenia. When patients present with purpura fulminans/DIC with genetic proclivity (thrombophilias) or with rapidly growing organisms (meningococcus), the process is deadly, unless reversed. Tissue factor is exposed by endothelial injury and is released into the bloodstream. If tissue factor is unmatched by tissue factor pathway inhibitor, it activates factor VII-mediated coagulation. Ongoing coagulation consumes clotting factors (including fibrinogen), antithrombotic factors (antithrombin III and protein C), and platelets; this leads to a state of massive clotting and sometimes bleeding. Therapeutic strategies must restore a homeostatic milieu by removing or inhibiting tissue factor activity and replacing anticoagulant factors, procoagulant factors, and platelets. If systemic clotting is limb-threatening or life-threatening, fibrinolytic therapies may be required for reperfusion. Debate continues on whether specific therapies (e.g., antithrombin III, protein C, heparin, or tissue plasminogen activator), nonspecific therapies (fresh frozen plasma and platelet replacement or plasma exchange), or a combination of both (plasma exchange plus antithrombin III or protein C), with tissue plasminogen activator added for limb- or life-threatening thrombosis) is best. Some investigators think that patients with meningococcemia cannot activate protein C,⁶⁹ whereas others have shown that these children can activate protein C.⁷⁰ Thus far, there is no evidence on the benefit of either product. Studies using intensive plasma exchange therapy appears to be of benefit because plasma exchange reverses both fibrin and platelet-vWF multimer-mediated thrombosis.⁷¹⁻⁷³

Nutrition, Electrolytes, Endocrine, and Metabolism

It is debated whether one should feed patients enterally when in shock; however, there is agreement that the enteral route is best when shock resolves. Total parenteral nutrition should be considered in patients not tolerating enteral feeds and “calories given” directed to “calories expended” if a metabolic monitor is available. If a monitor is not available, calorie needs can be overestimated when using classic formulas in critically ill children. Hypoglycemia should be rigorously avoided and treated. Hypoglycemia is associated with devastating neurologic outcomes. Strict control of hyperglycemia with insulin infusion substantially reduced mortality in a pediatric ICU by reducing deaths from multiple organ dysfunction syndrome/multiple organ failure.⁷⁴ In general, infants are at risk of developing hypoglycemia when they depend on IV fluids; a glucose intake of 4 to 6 mg/kg/min or maintenance fluid intake with glucose 10% and sodium chloride 0.45% is advised.

Immunomodulation

Children whose system cannot kill invading organisms die from sepsis. Primary and acquired immunodeficiency states must be treated. Children with chronic granulomatous disease require white blood cell transfusions and interferons. Patients with hypogammaglobulinemia require treatment with IV immunoglobulin. Granulocyte macrophage colony-stimulating factor was shown to improve survival in newborn neutropenic septic shock in randomized controlled trials.^{75,76} Transplant and nontransplant patients who develop septic shock while receiving immunosuppression die unless the immunosuppressants are rapidly tapered. Polyclonal IV immunoglobulin has been reported to reduce mortality rate and is a promising adjuvant in the treatment of sepsis and septic shock. The number of trials with children has been small, however, and the totality of the evidence is insufficient to support a robust conclusion of benefit. Adjunctive therapy with monoclonal IV immunoglobulin is experimental.⁷⁷

Drug Dosing

Decreased cytochrome P450 activity is manifested in impaired steroid synthesis and impaired drug metabolism is present in children with

sepsis, septic shock, or multiple organ failure. Patients with multiple organ failure are at particular risk of toxicity with drugs that are metabolized by the cytochrome P450 system. Renal function is also impaired. Creatinine clearance-directed drug dosing of renally eliminated drugs is necessary in these patients. Drugs should be administered according to pharmacodynamic and pharmacokinetic goals.

SOME MULTICENTER RANDOMIZED CONTROLLED TRIALS FOR PEDIATRIC SEPTIC SHOCK

deOliveira and colleagues observed a greater than threefold reduction in mortality when using ACCM-PALS therapies directed to RA/SVC or RA/IVC oxygen saturations over 70%.⁶³ The intervention arm received more fluids, blood, and inotrope/vasodilators than the non-intervention arm. In two trials, neither vasopressin nor terlipressin was effective in improving outcomes in refractory vasodilated shock.^{78,79}

Ventura and colleagues demonstrated that peripheral epinephrine is superior to peripheral dopamine in children with fluid refractory shock without central access (mortality rate 20% with dopamine, 7% with epinephrine).⁴⁸

KEY POINTS

1. The mortality by severe sepsis in neonatal and pediatric patients has improved from 97% in 1963 to 9% in 1999 to about 4% in 2003. Previously healthy children have better outcomes than children with chronic illness.
2. Although outcomes are improving, the burden of newborn and pediatric sepsis is increasing in the United States. More children die with severe sepsis than with cancer, with an estimated yearly healthcare cost of \$4 billion in the United States for patients with this condition.
3. The physiologic differences in coagulation and fibrinolysis between adults and children might lead to an earlier exhaustion of coagulation factors and disseminated intravascular coagulation in infants and young children.
4. In contrast to adults, death from shock in children is most commonly associated with progressive cardiac failure, not vascular failure. Pediatric patients have low cardiac output/high systemic vascular resistance (60%), low cardiac output/low vascular resistance (20%), or high cardiac output/low vascular resistance (20%).
5. Genetic polymorphisms in components of the inflammatory pathways have been shown to be involved in the susceptibility, severity, and outcome of pediatric sepsis.
6. Published in 2007, the American College of Critical Care Medicine evidence-based *Clinical Practice Parameters for Hemodynamic Support of Newborns and Children with Septic Shock* were based, in part, on the concept that early recognition and resuscitation improve outcome.
7. The moment of intubation should be estimated on the basis of clinical diagnosis of respiratory distress or hemodynamic instability, not on blood gas analysis.
8. Many children with shock require aggressive volume resuscitation. Unless hepatomegaly, cardiomegaly, or crackles are present, this should be given as 20-mL/kg boluses of normal saline or colloid to a total of 60 mL/kg in the first 10 to 20 minutes, while peripheral epinephrine is being started and the airway is being managed.
9. Development of multiple organ failure is observed with delayed resuscitation and source control. Patients with multiple organ failure commonly have inflammation phenotypes that can respond to personalized therapies.

Infections in the intensive care unit (ICU) contribute significantly to patient morbidity. Depending on the type of ICU, nosocomial infections may account for 70% of infections.¹ Nosocomial infections of the urogenital tract are frequent and sometimes underestimated in the ICU.²

DEFINITION

Urinary tract infection (UTI) can be the primary cause for admission to the ICU or can be acquired after intensive care procedures. Because patients are frequently sedated in the ICU, clinical diagnosis of UTI is often difficult. Nevertheless, UTI is an important cause of morbidity and antibiotic resistance in the ICU. Complicated UTI is a very heterogeneous entity, with a common pattern of the following factors^{3,4}:

- Anatomic, structural, or functional alterations of the urinary tract, which significantly impede urodynamic properties (e.g., stents, urine transport disturbances, instrumentation of the urinary tract, stones, tumors, or neurologic disorders)
- Impaired renal function due to parenchymal diseases or pre-, intra-, or postrenal nephropathies (e.g., acute and chronic renal insufficiencies, cardiac insufficiency)
- Accompanying diseases impairing the patient's immune status (e.g., diabetes mellitus, liver insufficiency, use of immunosuppressive agents such as corticosteroids, acquired immunodeficiency syndrome (AIDS), or hypothermia)

ETIOLOGY

Causative pathogens of UTI are almost exclusively bacteria and yeast. Viral pathogens are only found in patients with severe immunosuppression, such as after bone marrow transplantation. High antibiotic pressure and special circumstances in the ICU modulate the microbial spectrum. *Escherichia coli* is the most frequent pathogen but occurs less frequently than in uncomplicated community-acquired UTI. Other Enterobacteriaceae may also be uropathogens (e.g., *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, or *Morganella* species). Nonfermenters such as *Pseudomonas aeruginosa*, gram-positive cocci such as staphylococci and enterococci, and *Candida* species may also play an important role. The microbial spectrum is likely to differ over time and from one institution to the other. To follow the spectrum and development of antibiotic resistance, each ICU has to update its own analyses (Table 123-1, Fig. 123-1).

EPIDEMIOLOGY

The Extended Prevalence of Infection in Intensive Care (EPIC II) study¹ revealed that 51% of patients were infected on the study day and that 71% of all patients were receiving antibiotics. The most frequent types of ICU-acquired infections with their total occurrence were respiratory tract infections, 63.5%; abdominal infections, 19.6%; bloodstream infections, 15.1%; and renal or UTIs, 14.3%.¹ The true incidence of UTI, however, may be even higher if meticulously looked for. In a prospective study specifically evaluating nosocomial UTI, nosocomial UTIs accounted for 28% of nosocomial infections, lower respiratory tract infections for 21%, pneumonia for 12%, and bloodstream infections for 11%. The rates of urinary catheter-associated

UTIs varied between 4.2% (symptomatic UTI) and 14.0% (asymptomatic UTI), which shows that asymptomatic bacteriuria is frequent in ICU patients, although symptoms of UTIs in intensive care patients are frequently difficult to assess.² In the global one-day point prevalence study in urologic hospitalized patients (GPIU study), asymptomatic bacteriuria accounted for 27% of health care-associated (HA) UTIs, followed by cystitis (26%), pyelonephritis (20%), urosepsis (11%), and other urogenital infections (16%),⁷ showing that HA UTI is present in high frequency in certain patient groups.

UTIs in the ICU are divided into two groups:

1. UTIs with nonurologic complicating causes: diabetes mellitus, renal insufficiency, immunodeficiency, infectious foci contiguous to the urogenital tract, or trauma patients
2. UTIs with urologic complicating causes: renal transplantation, neurogenic bladder dysfunction, procedures in the urogenital tract, urinary stones or foreign bodies in the urogenital tract

In UTIs with primary nonurologic complicating causes, antimicrobial therapy is generally sufficient. However, in UTIs with primary urologic causes, the complicating factors must be identified and treated. In such cases, antimicrobial therapy is only one component of the treatment.

Urinary Tract Infections with Nonurologic Complicating Causes

Individuals with diabetes are at higher risk of UTIs.^{8,9} Increased susceptibility in patients with diabetes is positively associated with the increased duration and severity of diabetes as a result of impaired granulocyte function, decreased excretion of the Tamm-Horsfall protein, low levels of interleukin (IL)-6 and IL-8 in the urine that lead to lower "cidality" of the urine, and altered microflora in the genital region. In addition, diabetic cystopathy and nephropathy may be complicating factors in the urinary tract. In addition to antibiotics, treatment must address the metabolic situation. In pyelonephritis, usually, a switch to insulin or insulin-analogous therapy is necessary.

The place of immunosuppression per se in the development of UTI remains unresolved.¹⁰ Patients with end-stage renal failure are generally not particularly susceptible to the usual gram-negative urinary pathogens, although they may acquire unusual and granulomatous infections. Patients have evidence of reduced cellular and humoral immunity. However, the situation is a little clearer in male patients with HIV and AIDS, where there is a close relationship between CD4 counts and the risk of bacteriuria, particularly in those whose counts are less than 200 cells/mL.¹¹

Pathogens may be translocated into the urinary tract from contiguous infectious foci (e.g., appendicitis, sigmoid diverticulitis, or translocation by ileus). Symptoms and localization of pain can be misleading and may delay the diagnosis. Operations or trauma may cause hypothermia, tissue hypoxia, and hemodynamic alterations that result in kidney dysfunction and impaired mucosal perfusion. The use of latex catheters in these critical situations (e.g., operations with heart-lung machine) can also lead to urethral strictures. Silicone catheters or suprapubic catheters are recommended in these patients.¹² Suprapubic catheters cannot prevent UTIs. They can, however, lower the rate of UTIs from 40% to 18%.¹³

Urinary Tract Infections with Urologic Complicating Causes

Patients show a high risk of developing bacteriuria after renal transplantation, threatening clinical outcomes for both the patient and

transplant. Early infections (up to 3 months after transplantation) are differentiated from late infections (more than 3 months after transplantation). Early infections may present with no symptoms. In this phase, occult bacteremia (60% of bacteremias after renal transplantation originate from the urinary tract), allograft dysfunction, and recurrent

UTIs after antibiotic therapy are frequently seen.⁴ Sometimes, it can be very difficult to distinguish rejection from infection. Patients must also be investigated for surgical complications.

UTIs caused by *Candida* species are frequently asymptomatic. There is, however, a risk of obstructive fungal balls leading to candidemia or invasion of the anastomosis in renal transplant recipients. Asymptomatic candiduria should therefore be treated in these patients.⁴ Urine transport disturbances (e.g., from an obstructive ureteral stone) require specific urologic therapy such as percutaneous nephrostomy or stenting. In case of bladder obstruction, an indwelling urinary catheter (suprapubic or transurethral) will be the primary therapy in the ICU. Long-term indwelling catheters (more than 30 days) are associated with a selected microbial spectrum of difficult-to-treat uropathogens (e.g., *Providencia* spp., *Proteus* spp., or *Pseudomonas* spp.).¹⁴ After initiation of antimicrobial therapy, the catheter should be replaced to remove the biofilm material.⁴

■ PATHOPHYSIOLOGY

UTIs generally occur from organisms invading the urinary tract via the urethra. Pathogens originate from endogenous or exogenous nosocomial flora. Hematogenous spread to the urinary tract is rare.

In uncomplicated UTIs, pathogens need to have very specific virulence factors enabling them to initiate an infection after the invasion of the urinary tract. The medical conditions of an ICU patient may weaken physiologic barriers and defenses, thus facilitating the entry of pathogens. In addition, the nosocomial environment in the ICU, including antibiotic pressure and decreased supply of oxygen or nutrients (e.g., iron) to tissues, can select pathogens with specific resistance patterns. A general adaptation strategy is the formation of hypermutator strains, which show 100- to 1000-fold increased mutation frequencies, enabling the pathogens to rapidly adapt to challenging environments and thus develop effective mechanisms for antibiotic resistance.^{15,16}

An important mechanism contributing to UTI is the formation of biofilms, which is associated with the increased number of biomaterials used in medical practice. Biofilm infections develop not only around foreign bodies such as urinary catheters or stents but also in urinary stones, scar or necrotic tissue, obstructive uropathies, or even chronic bacterial prostatitis. A biofilm has been defined as an accumulation of microorganisms and their extracellular products, forming a structured community on a surface. The formation of a biofilm generally consists of three steps:

1. Deposition of a host conditioning film
2. Attachment of microorganisms followed by microbial adhesion and anchorage to the surface by exopolymer production
3. Growth, multiplication, and dissemination of the organisms

The basic structural unit of a biofilm is a microcolony—that is, a discrete matrix-enclosed community consisting of bacteria of one or more species. The biofilm is usually built up of three layers.^{12,13}

1. Linking film that attaches to the surface of a tissue or biomaterial
2. Base film of compact microorganisms
3. Surface film as an outer layer, where planktonic organisms can be released to float freely and spread on the surface

Bacteria within biofilms differ both in behavior and phenotypic form from the planktonic, free-floating bacteria. The failure of antimicrobial agents to treat biofilms has been attributed to a variety of mechanisms:

- Organisms encapsulated in biofilms grow more slowly than planktonic ones, probably because encapsulated bacteria have a decreased nutrient and oxygen supply, leading to a decreased metabolic rate and antimicrobial susceptibility. This may select a less susceptible genotype, forming a resistant population. Furthermore, antimicrobial binding proteins are poorly expressed in these slow-growing bacteria.
- The biofilm matrix delays or impedes the diffusion of antibiotic molecules into the deeper layer of the film (extrinsic resistance).

- Bacteria within the biofilm are phenotypically so different from their planktonic counterparts that antimicrobial agents fail to eradicate them. Bacteria within a biofilm activate many genes that alter the cell envelope and molecular targets by altering the susceptibility to antimicrobial agents (intrinsic resistance). These phenotypic changes are likely to play a more important role in the development of antimicrobial resistance than external resistance (biofilm matrix, glycocalyx).
- Bacteria within a biofilm can sense the external environment, communicate with each other, and transfer genetic information and plasmids within biofilms.
- Bacteria in biofilms can usually survive antibacterial concentrations 100 to 150 times higher than those needed to kill planktonic bacteria of the same species.¹⁷⁻¹⁹

Antimicrobial treatment can be effective in only “young” biofilms (<24 hours). At present, combination therapy with fluoroquinolones and macrolides or fosfomycin seems to be most effective against biofilm infections. During an acute febrile phase of biofilm infection, antimicrobial therapy is essential and can be effective because the planktonic bacteria are responsible for the febrile reactions and not the bacteria covered in the biofilm. However, to eradicate pathogens from the biofilm, the biofilm itself has to be removed (e.g., catheter change or extraction of infectious stones).

■ DIAGNOSIS

Medical History and Physical Examination

Sedated intubated patients are often difficult to evaluate regarding their signs and symptoms of UTIs. The patient or a family member should be asked about previous episodes of UTIs as well as urologic diseases (e.g., stones or tumors) or operations.

The physical examination should include inspection and palpation of the costophrenic area, lower abdomen, pubic region, inguinal lymph nodes, and genitals and a digital transvaginal or transrectal examination. Ultrasound is an important diagnostic device, and its use should be frequently considered because of the close proximity of the urogenital organs to the intestine, spleen, liver, pancreas, gallbladder, ovary, or uterus.

Urinary Examinations

Urine specimens in ICU patients are almost exclusively collected from catheters. Because urine from catheters has to be collected into a closed system, the urine specimen should be taken from the puncture site at the catheter after disinfection, without opening the closed system. There are different complementary methods for laboratory examination of the urine specimen.

Dipstick Test

The dipstick test is performed with undiluted urine and investigates the following infection-related parameters²⁰:

- pH: an alkaline urine (pH > 8.0) points to urease-producing organisms such as *Proteus* or *Providencia* spp. and is associated with magnesium-ammonium-phosphate stones.
- Nitrate: most Enterobacteriaceae harbor a nitrate reductase that reduces nitrate to nitrite. Some common uropathogens such as *Enterococcus* and *Staphylococcus* lack nitrate reductase and will therefore not be detected using this parameter, independent of their urinary concentration. The positive detection of nitrate requires its inclusion in the patient's diet.
- Leukocytes (positive leukocyte esterase): granulocytes are the most frequently detected leukocytes in the urine of UTI patients. Macrophages appear fairly often in patients with UTIs, but their significance remains unknown.
- Erythrocytes (positive hemoglobin): hematuria remains a major sign of urinary tract and renal disease.
- Specific gravity/osmolality (degree of urine dilution)

TABLE 123-2

Division and Dosage of Distinct Antibiotics Recommended for Treatment of Urinary Tract Infections

| ANTIBIOTIC GROUP | SUBSTANCE | DOSAGE | |
|----------------------------|-----------------------------|---|--|
| | | ORAL | IV |
| Aminopenicillin + BLI | Ampicillin/sulbactam | 0.750 g twice daily | 0.75-3 g 3 times daily |
| | Amoxicillin/clavulanic acid | 1 g twice daily <i>or</i> 0.625 g 3 times daily | 1.2-2.2 g 3 times daily |
| Acylureidopenicillin + BLI | Piperacillin/tazobactam | — | 2.5-4.5 g 3 times daily |
| | Piperacillin/sulbactam | — | 5 g 3 times daily |
| Cephalosporin Gr. 1 | Cephalexin | Prophylaxis only | — |
| Cephalosporin Gr. 2 | Cefuroxime axetil | 500 mg twice daily | — |
| | Cefuroxime | — | 0.75-1.5 g 3 times daily |
| | Cefotiam | — | 1-2 g 2-3 times daily |
| Cephalosporin Gr. 3 | Cefpodoxime proxetil | 200 mg twice daily | — |
| | Ceftibuten | 200-400 mg daily | — |
| Cephalosporin Gr. 3a | Cefotaxime | — | 1-2 g 2-3 times daily |
| | Ceftriaxone | — | 1-2 g daily |
| Cephalosporin Gr. 3b | Ceftazidime | — | 1-2 g 2-3 times daily |
| Cephalosporin Gr. 4 | Cefepime | — | 2 g twice daily |
| Cephalosporin + BLI | Ceftolozane/tazobactam | — | Ceftolozane/tazobactam 1.5 g 3 times daily |
| | Ceftazidime/avibactam | — | Ceftazidime/avibactam 2.5 g 3 times daily |
| Carbapenem Gr. 1 | Imipenem | — | 0.5-1 g q 6-8 h |
| | Meropenem | — | 0.5-1 g 3 times daily |
| | Doripenem | — | 0.5 g 3 times daily |
| Carbapenem Gr. 2 | Ertapenem | — | 1 g daily |
| Fluoroquinolone Gr. 2 | Ciprofloxacin | 500-750 mg twice daily | 400 mg twice daily |
| | Ciprofloxacin XR | 1000 mg daily | — |
| Fluoroquinolone Gr. 3 | Levofloxacin | 500-750 mg daily | 500-750 mg |
| ANTIMYCOTIC GROUP | | | |
| Azole derivatives | Fluconazole | 400-800 mg daily | 400-800 mg daily |
| | Voriconazole | 4-6 mg/kg BW daily | 4-6 mg/kg BW daily |
| Pyrimidine analog | Flucytosine | — | 100-150 mg/kg BW 4 times daily |
| Echinocandin | Caspofungin | — | 50-70 mg daily |

BLI, β -lactamase-inhibitor; BW, body weight; IV, intravenous.

Data from (4).

- Protein; total protein in urine is a mixture of high- and low-molecular-weight plasma proteins from the kidney and urinary tract or bacteria.
- Glucose (metabolic condition of the patient)

Microscopy

There are two possibilities of a microscopic evaluation²⁰:

1. Chamber counting of uncentrifuged urine (standard values for urine shown in Table 123-2).
2. Urinary sediment findings; at least 10 fields of vision at 400 \times magnification are counted, and the mean value of particles is registered. However, centrifugation methods are never quantitative in counting erythrocytes and leukocytes because of variable loss during centrifugation.

Microbiology

To differentiate contamination in urine from significant bacteriuria, quantitative microbiology is needed. The microbial count has to be interpreted in relation to the urinary dilution.

Clinical Diagnosis

To survey and compare infection rates in different institutions, UTIs should be classified according to widely accepted definitions, such as the definitions of the U.S. Centers for Disease Control and Prevention (CDC). The CDC/National Healthcare Safety Network definitions²¹ stratify HA UTIs into symptomatic, asymptomatic, and other infec-

tions of the urinary tract. To be of value in determining a nosocomial infection, urine specimens must be obtained aseptically using an appropriate technique such as clean catch collection, bladder catheterization, or suprapubic aspiration.

THERAPY

General Principles

Not all bacteriuric patients in the ICU need to be treated. In general, asymptomatic bacteriuria does not have to be treated.²² Therapy should only be started in patients with significant symptoms and morbidity and in whom asymptomatic bacteriuria may be deleterious (e.g., before traumatizing intervention of the urinary tract and in pregnant women). In the ICU, indications for treatment of asymptomatic UTIs might include some other circumstances such as renal transplant, severe diabetes mellitus, or severe immunosuppression. In complicated UTIs, antibiotic therapy can only be successful when complicating factors can be eliminated or urodynamic functions restored. Treatment of complicated UTIs therefore comprises adequate antibiotic treatment and successful urologic intervention.

Antibiotic Therapy

For therapy of complicated UTI, antibiotics must possess appropriate pharmacodynamic and pharmacokinetic prerequisites: high renal

unmetabolized clearance with good antibacterial activity, both in acidic and alkaline urine. Moreover, microbial resistance patterns must be considered in the choice of antibiotics. Increasing antibiotic resistance, especially among Enterobacteriaceae, makes prudent antibiotic therapy increasingly difficult. The increasing appearance of quinolone-resistant and extended-spectrum β -lactamase (ESBL)-forming enterobacteria will inevitably lead to the increased use of carbapenems in the empiric therapy, thus increasing the antibiotic pressure on these highly potent antibiotics. To diminish the selection pressure for resistant pathogens, antibiotics from different classes should be used. Multiple antimicrobial agents are available for therapy for complicated UTIs (see Table 123-2): second- or third-generation cephalosporins, broad-spectrum penicillins with β -lactamase inhibitors, monobactams, and carbapenems. For empiric therapy for severe UTIs, broad-spectrum antibiotics should be used (e.g., broad-spectrum penicillins with β -lactamase inhibitors, third-generation cephalosporins, fluoroquinolones, or carbapenems). Synergism with aminoglycosides, which inhibit protein synthesis and thus block the formation of toxins or virulence factors, might be useful for initial therapy, but side effects have to be considered.

Candiduria is a common problem in ICUs. It may represent harmless colonization, but it can also be an early sign of systemic candidosis.²³ A second urine culture after replacing the urethral catheter can rule out contamination. In critically ill patients, systemic therapy for *Candida* species should be started according to susceptibility testing or species differentiation (see Table 123-2). Complicating factors such as diabetes mellitus or urologic abnormalities should be treated concomitantly. Systemic antimycotic therapy is preferred to local instillation therapy because of the potentially systemic nature of candiduria in ICU patients.

Urologic Therapy

Urologic interventional therapy of complicated UTIs is divided into acute therapy and delayed drainage therapy. The primary aim of acute therapy is improved urinary flow, with minimal patient contamination by infected urine. In primary therapy, catheters, stents, or drains are frequently used. Delayed drainage therapy of the urinary tract (e.g., lithotomy, prostatic resection, or ureter reimplantation) is frequently performed after days or weeks of stabilization.

Prophylaxis of Catheter-Associated Urinary Tract Infections

Some 80% to 90% of nosocomial UTIs are associated with urinary catheters or instrumentation of the urinary tract. The best prophylaxis is to avoid a catheter or, if catheterization is necessary, to minimize catheter duration. Various techniques have been used to avoid catheter-related infections.

Silver coating of catheters may exert a bactericidal effect, but the concentration of free silver ions must be high, whereas the exposure to albumin and chloride ions has to be low because silver-chloride complexes can precipitate.²⁴ A multicenter randomized controlled trial using silver alloy- or nitrofurantoin-coated catheters in adults requiring short-term catheterization in hospital could not demonstrate a sufficiently high reduction in symptomatic UTIs to recommend routine use of antimicrobial-impregnated catheters.²⁵ Suprapubic catheterization can initially decrease the rate of UTIs from 40% to 18% because the proximity to the anal region and the irritation of the urethral mucosa with ensuing mucopurulent discharge are avoided.¹³ Urinary drainage should be performed with a closed system that should not be opened either for emptying or for urinary sampling. The sites used for urinary sampling must be adequately sterilized. General hygienic procedures such as aseptic catheter insertion, wearing of disposable gloves, and hygienic hand disinfection to prevent cross-contamination or cross-infection are mandatory. International consensus recommendations for the use of urinary catheters to prevent HA infections have recently been described.²⁶

Recommended Evidence-Based Measurements for Preventing Catheter-Associated Urinary Tract Infections

The primary methodologies for preventing catheter-associated UTIs²⁶ include:

- Limiting unnecessary catheterization and discontinuing the use of the catheter as early as possible
- Policies and procedures for recommended catheter insertion indications, insertion and maintenance techniques, discontinuation strategies, and replacement indications should be developed and closely followed.
- Alternatives to indwelling urethral catheterization should be considered, such as condom catheterization, intermittent catheterization, or suprapubic catheterization, although data are insufficient to recommend one alternative over another.
- Closed catheter drainage systems should be used.
- Most other measures for the prevention of catheter-associated UTIs, such as prophylaxis with systemic antimicrobials, methenamine salts, cranberry products, enhanced meatal care, and catheter irrigation with either antimicrobials or saline, are not recommended.²⁶
- It is also unclear whether routine catheter changes reduce the risk of catheter-associated bacteriuria or UTIs.

SPECIAL CLINICAL ISSUES

Infections of the Upper Urinary Tract and Contiguous Organs

Pyelonephritis

The high osmolality of the renal medulla has a negative effect on leukocyte function. For this reason, the interstitium of the renal medulla is more affected in pyelonephritis than the cortex. Clinical symptoms are unilateral or bilateral flank pain, painful micturition, dysuria, and fever ($>38^{\circ}\text{C}$). Focal nephritis is limited to one or more renal lobules, which is comparable to that in lobular pneumonia. Ultrasonographic findings are circumscribed lesion with interrupted echoes that breaks through the normal cortex/medulla organization. A computed tomography (CT) scan shows typical wedge-shaped, poorly limited areas of diminished sonographic density. As differential diagnoses, renal abscess, tumor, and renal infarction must be taken into account. Emphysematous pyelonephritis characteristically shows gas formation in the renal parenchyma and perirenal space. Diabetes mellitus or obstructive renal disease is the predisposing factor. The most frequently isolated organisms are *E. coli*, *Klebsiella pneumoniae*, and *Enterobacter cloacae*. Fermentation of glucose in Enterobacteriaceae occurs via two different metabolic pathways: mixed acid fermentation and the butylene glycol pathway. Organisms of the *Klebsiella-Enterobacter-Hafnia-Serratia* group and, to a lesser extent, *E. coli*, use the butylene glycol pathway and produce copious amounts of CO_2 , which appears clinically as gas formation.²⁷ Aggravated by diminished tissue perfusion, the contralateral side is often affected as well.

Renal and Perirenal Abscess

Clinical symptoms are rigor, fever, back or abdominal pain, flank tenderness, mass lesion and redness of the flank, and tenderness of the upper lumbar and paraspinal muscles. Respiratory insufficiency, hemodynamic instability, or reflexory paralytic ileus occurs frequently. Frequent signs of renal abscess formation are fever and leukocytosis for more than 72 hours, despite antibiotic therapy. The urinary culture may be negative in 14% to 20% of cases.²⁸ Frequently isolated organisms are *E. coli*, *K. pneumoniae*, *Proteus* spp., and *Staphylococcus aureus* from hematogenous spread. The fascial limitations are open toward the pelvis, and the perirenal fat is in close contact with the pelvic fat tissue. A perinephritic abscess may therefore point to the groin or perivesical

tissue or to the contralateral side, thus penetrating the peritoneum. Inflammation of the flank, thigh, back, buttocks, and lower abdomen may occur. Because of the late diagnosis, the mortality can be as high as 57%. Blood cultures are positive in 10% to 40% of cases, and urinary cultures are positive in 50% to 80%.²⁹

Infections of the Lower Urinary Tract and Contiguous Organs

Cystitis

Cystitis is frequently limited to the bladder mucosa and hence shows no systemic signs or symptoms. An ascending infection can, however, clinically result. Cystitis in the ICU is almost exclusively catheter-associated and can cause hematuria. Spontaneous elimination is frequently found after removal of the indwelling catheter but is less frequent in elderly patients.⁴

Epididymitis/Orchitis

Epididymitis in the ICU is usually an ascending infection and can also involve the testis. Possible causes are subvesical obstruction, transurethral resection of the prostate, or an indwelling transurethral urinary catheter, in which case the pathogens are identical with the pathogens in the urine. Of note, epididymitis is frequently involved in urogenital tuberculosis. Orchitis with the formation of a sterile hydrocele can appear during the course of polyserositis or cardiac failure and may point to a generalized systemic disease.

Cavernitis

Cavernitis of the penis is a rare phlegmonous infection of the cavernous bodies. Possible causes are indwelling transurethral urinary catheters, penile operations, autoinjection for erectile dysfunction, pelvic operations, or trauma. Pathogens may represent skin flora or uropathogens. Treatment consists of suprapubic catheterization, broad-spectrum antibiotic therapy, and, if needed, operative débridement.

Acute Prostatitis and Prostatic Abscess

Acute prostatitis and prostatic abscess are bacterial infections of the prostate gland. The bacterial spectrum consists of 53% to 80% *E. coli* and other enterobacteria, 19% gram-positive bacteria, and 17% anaerobic bacteria.³⁰ In regions with a high incidence of *Neisseria gonorrhoeae*, the prostate may be involved. Symptoms are high fever, rigor, dysuria, urinary retention, and perineal pain. Rectal palpation reveals an enlarged, tender prostate. Prostate massage is contraindicated. In acute prostatitis, the pathogens are usually detected in the urine. However, the urine may be sterile in prostatic abscess formation. Therapy consists of a combination of antibiotic therapy with broad-spectrum antibiotics

as well as the insertion of a suprapubic catheter. In case of a prostatic abscess, urologic drainage is necessary.³⁰

Fournier's Gangrene

Fournier's gangrene is a necrotizing fasciitis of the dartos and Colles fascias. It is mainly seen in men in the fourth to seventh decades but also occurs in women or newborns. Causes are operations or trauma in the genital or perineal region, including microlesions, or infectious processes from the rectal or urethral areas. Important predisposing factors are diabetes mellitus, liver insufficiency, chronic alcoholism, hematologic diseases, or malnutrition. Patient-related predictors of mortality are increasing age, increased Charlson comorbidity index, preexisting conditions such as congestive heart failure, renal failure or coagulopathy, and hospital admission via transfer.³¹ Fatality rates were 7.5% in one large study.³² The infectious process follows anatomically preformed spaces. The superficial perineal fascia is fixed dorsally at the transverse deep perineal muscle and laterally at the iliac bone and merges ventrally in the superficial abdominal fascia. Hence, a ventrally open and craniodorsally and laterally closed space is formed (Colles space), which facilitates the spread of infection. In contrast to gas gangrene, the fascial borders are respected in Fournier's gangrene. A mixed bacterial flora is seen, consisting of gram-positive cocci, enterobacteria, and anaerobic bacteria. The released toxins facilitate platelet aggregation and complement activation, which, in conjunction with the release of heparinase by anaerobic bacteria, lead to small vessel thrombosis and tissue necrosis. The destruction of tissue enhances the potential of acute renal failure. Fournier's gangrene is a rapidly progressing infection that leads to septic shock if not treated in time.

Therapy for Fournier's gangrene consists of immediate operative débridement, followed by subsequent operations until the infectious process has been controlled. A suprapubic catheter is advisable, and colostomy may have to be performed in cases where fecal contamination of the wound is inevitable. A combination of antibiotic therapy with broad-spectrum β -lactam antibiotics, fluoroquinolones, and clindamycin is recommended.

Urosepsis

In 20% to 30% of all septic patients, the initial infectious focus is in the urogenital tract. The most frequent causes for urosepsis are obstructive diseases of the urinary tract such as ureteral stones, anomalies, stenosis, or tumor. Early relief from the obstruction controls the infectious focus and improves organ perfusion. This is one reason why mortality in urosepsis is usually lower than that in other septic forms (Fig. 123-2).³³

FIGURE 123-2 ■ 612 Episodes of gram-negative bacteremia 1965-1974.³³

Immediately after microbiological sampling of urine and blood, empiric broad-spectrum antibiotic therapy should be started parenterally. Adequate initial (e.g., in the first hour) antibiotic therapy ensures improved outcome in septic shock.^{34,35} Inappropriate antimicrobial therapy in severe UTIs is linked to a higher mortality rate.³⁶ Empiric antibiotic therapy is based upon the expected bacterial spectrum, institution-specific resistance rates, specific pharmacokinetic and pharmacodynamic factors in UTIs, and individual patient characteristics.

The bacterial spectrum in urosepsis predominantly consists of Enterobacteriaceae such as *E. coli*, *Proteus* spp., *Enterobacter* and *Klebsiella* spp., nonfermenting organisms such as *P. aeruginosa*, and gram-positive organisms.³⁷⁻³⁸ *Candida* spp. and *Pseudomonas* spp. occur as causative agents in urosepsis mainly if the host defense is impaired. Patients with candiduria show frequently invasive candidiasis and candidemia.^{39,40} Candiduria at any time in an ICU is associated with higher mortality rates (OR, 2.86).⁴⁰ Viruses are not common causes of urosepsis.

Although urosepsis is a systemic disease, the activity of an antibiotic at the site of the infection is critical. A variety of studies have shown that inflammatory mediators such as IL-6, CXC chemokines, endotoxin, or HMGB1 are produced and released in the urinary tract.⁴¹⁻⁴³ Therefore, predominantly antimicrobial substances with high activities in the urogenital tract are recommended.^{44,45}

The increasing antibiotic resistance rates of pathogens causing urosepsis significantly diminish the choice of antibiotics available for adequate empiric initial therapy in urosepsis. In particular, the increasing rates of Enterobacteriaceae producing ESBL pose clinically relevant problems.^{5,46-48} Other recent developments of concern include increased rates of fluoroquinolone-resistant enterobacteria and vancomycin-resistant enterococci.^{49,50} Currently, there are no specific pharmacokinetic/pharmacodynamic parameters available for the treatment of patients with urosepsis.

Correct dosing in urosepsis has to consider the altered systemic and especially renal pathophysiology that exists in patients with urosepsis. Sepsis and the treatment thereof result in higher clearances of antibacterial drugs.⁵¹ The increased volume of distribution as a result of peripheral edema in sepsis will lead to underexposure, especially of hydrophilic antimicrobials such as β -lactams and aminoglycosides, which exhibit a volume of distribution mainly restricted to the extracellular space.⁵² Increased dosing is therefore necessary. On the other hand, urosepsis may also cause multiple organ dysfunction such as hepatic or renal dysfunction, resulting in decreased clearance of antibacterial drugs. In such a case, dosing adjustment has to be considered. As β -lactams are time-dependent antibacterials, optimal administration would be by continuous infusion. Fluoroquinolones, on the other hand, display largely concentration-dependent activity. The volume of distribution of fluoroquinolones in sepsis is not greatly influenced by fluid shifts, and therefore, no alterations of standard doses are necessary, unless renal dysfunction occurs.^{51,52}

Depending on local susceptibility patterns, a third-generation cephalosporin, piperacillin, in combination with a β -lactamase inhibitor or a carbapenem may be appropriate for empiric therapy.^{4,53-56} In areas with

a high (>10%) rate of Enterobacteriaceae producing ESBL, initial treatment with a carbapenem might be advisable.⁵³⁻⁵⁷ Aminoglycosides as monotherapy might be an alternative; however, data supporting monotherapy in patients with urosepsis are not sufficient. In case of candiduria with signs of sepsis, antifungal treatment is recommended.^{39,40}

KEY POINTS

1. Complicated urinary tract infection (UTI) is a very heterogeneous entity with a common pattern of complicating factors.
2. The bacterial spectrum of complicated UTIs is much broader than that of uncomplicated UTIs, comprising a variety of gram-negative and gram-positive pathogens and, among these, frequently multiresistant pathogens.
3. UTIs are frequent in intensive care units (ICUs). It would be pragmatic to stratify UTIs into those with nonurologic complicating causes, in which antimicrobial therapy is the primary therapy, and those with urologic complicating causes, in which the complicating urologic anomaly has to be effectively treated.
4. Pathogens of nosocomial complicated UTIs may be characterized by certain properties such as adaptation strategies to changing environments (i.e., hypermutator strains) or propensity to biofilm formation.
5. The diagnosis of UTIs is based on medical history and a thorough physical examination, including bedside ultrasound as well as investigations of urine (dipstick test, microscopy, and microbiology). For clinical diagnosis, general accepted criteria should be employed. Symptomatic UTIs in ICU patients are especially difficult to evaluate.
6. Not all bacteriuric patients in ICUs need to be treated. Therapy should, however, be started early in those with significant symptoms and morbidity. Management of complicated UTIs comprises adequate antibiotic therapy and successful treatment of complicating factors.
7. Prophylaxis of UTIs is important. However, the percentage of infections that can be prevented is not known. Important points in prophylaxis encompass training of staff, hygiene measures, type of catheter and drainage, and patient care.
8. Special clinical pictures of UTIs and infections of contiguous organs are seen in the ICU. UTIs of the upper urinary tract are distinguished from those of the lower urinary tract and infections of the male adnexal glands and fasciitis of the perineum and scrotum. All these pictures can potentially merge into urosepsis if the UTI is not treated adequately. The urogenital tract is the source of sepsis in 20% to 30% of cases.

Central nervous system (CNS) infections represent life-threatening conditions that frequently require treatment in a critical care unit. These infections may be challenging to recognize as numerous noninfectious conditions may mimic CNS infections. For example, a necrotic brain tumor may be clinically and radiologically indistinct from a brain abscess. Similarly, distinguishing between viral and autoimmune encephalitis can be challenging. Even when an infectious syndrome is suspected, it may take several days before a specific microorganism is identified, necessitating the use of broad empiric therapy directed against the most likely causative pathogens based on clinical, epidemiologic, and demographic clues. Pharmacologic considerations in selecting appropriate antimicrobials include the ability of the agent to cross the blood-brain barrier and achieve bactericidal levels at the site of infection. Clinical outcomes associated with CNS infections are directly related to the rapidity with which appropriate medical or surgical interventions can be provided, adding urgency to the diagnostic and therapeutic evaluation.¹

CNS infections may be caused by bacteria, fungi, viruses, protozoa, and prions. The risk of infection with these pathogens varies based on the host immune status (e.g., human immunodeficiency virus [HIV] infection, organ transplantation), epidemiology (e.g., time of year, travel to endemic regions), and acquisition site (e.g., community acquired vs. health care acquired). The microbiology and pathophysiology of CNS infections differ based on the specific anatomic site of infection. The major CNS syndromes covered in this chapter include meningitis, brain abscess, encephalitis, and myelitis. These syndromes may occur in isolation or may be found as overlapping conditions (e.g., meningoencephalitis or encephalomyelitis). Localizing the site of infection is often the first step in guiding the diagnostic evaluation and initiating empiric therapy.

MENINGITIS

Infections of the meninges can be subclassified by the acuity of onset of symptoms. Bacterial infections almost exclusively cause an acute meningitis syndrome, characterized by rapid (<48 hours) progression of fever, headache, and meningismus. In contrast, subacute meningitis syndrome, which occurs frequently due to viruses, fungi, or mycobacteria, is more slowly evolving, with symptoms developing over several days to weeks (Box 124-1). The following sections outline approaches to acute meningitis and subacute CNS infection syndromes. These approaches prioritize the competing needs of obtaining a precise microbiological diagnosis versus instituting early antimicrobial therapy.

Anatomy

Bacterial meningitis is a pyogenic infection of the cerebral ventricles and the subarachnoid space, with bacteria usually confined to the nutrient-rich cerebrospinal fluid (CSF). In adults, CSF is produced at a rate of approximately 500 mL/day, yet the CSF space averages only 140 mL in volume; therefore, there is rapid production and reabsorption. CSF is formed in the choroid plexus of the ventricles, flows into the subarachnoid space at the cisterna magna and around the cerebral hemispheres, and is reabsorbed by the arachnoid villi (Fig. 124-1). The cerebral and spinal subarachnoid spaces connect at the cisterna magna

and the flow of CSF through the spinal subarachnoid space are of variable velocity and direction.

There are numerous potential and actual spaces among the layers of the meninges (Fig. 124-2). Meningitis involves the actual space (i.e., the subarachnoid space), which consists of multiple interconnected compartments. The small size of the foramina of Luschka and Magendie allows for a unidirectional caudal flow toward the cisterna magna, where the CSF then moves either cephalad or caudally into the spinal canal. This compartmentalization has implications in therapy because the movement of medications and infectious agents is influenced by the rate and direction of CSF flow. A blockage at any of these levels may restrict the entry of antibiotics into sites of ongoing infection.

Infectious agents can invade the CSF by at least three routes (Box 124-2). First, the vascular structures of the choroid plexus and pia and the vessels that traverse the subarachnoid space may serve as conduits during systemic bacteremia. A second less common route is by direct invasion across the protective meninges. Physical disruption of the dura by trauma or surgery allows for the direct invasion of the subarachnoid space and should be considered in patients with a history of CSF leakage or rhinorrhea, in addition to those who have undergone recent neurosurgical interventions. Emissary veins provide another pathway for bacteria to spread from contiguous foci into the subarachnoid space. These veins traverse the skull and dura, directly connecting the soft tissues of the head and neck with the venous system of the brain and meninges, including the arachnoid villi. Although blood in the emissary veins usually flows away from the brain, the CNS veins and dural sinuses do not contain valves, and retrograde flow of bacteria is possible. Rarely, organisms may reach the ventricles or subarachnoid space from within the neural tissue; for example, rupture of a brain abscess into the ventricles may have disastrous effects. Until recently, it was thought that the brain has no lymphatic drainage and that these recently identified vessels may prove to be another route of infectious contamination of the CNS.^{2,3}

Pathophysiology

A number of virulence factors contribute to the development of bacterial meningitis.⁴ Despite complex host-cellular and anatomic defense mechanisms including immune surveillance of the CSF,⁵ microorganisms have evolved a number of virulence factors to overcome these. Once in the CSF, bacteria induce leukocyte migration into the subarachnoid space, which can cause occlusion of cortical blood vessels, damage to nerve roots that traverse the subarachnoid space (see Fig. 124-2), and impaired CSF flow (see Fig. 124-1). The activation of leukocytes leads to an inflammatory cascade, with the release of cytokines, oxidants, and proteolytic enzymes, which contribute to the damage caused by the infection. The resultant edema can lead to increased intracranial pressure and a risk of herniation.⁶

Epidemiology

Prior to the availability of antibiotics, bacterial meningitis was universally fatal. However, even with the availability of effective antimicrobial therapy, the case fatality of bacterial meningitis remains roughly 25%, with a high incidence of neurologic sequelae among survivors.^{7,8}

BOX 124-1

Causes of Acute and Subacute Central Nervous System Infection Syndromes

ACUTE MENINGITIS SYNDROME

Rapid onset (<24–48 h) of fever, headache, or meningismus, with early cognitive impairment

Common

Pyogenic meningitis (pneumococcal, meningococcal, *Listeria*, other)

Uncommon

Viral encephalitis (especially herpes simplex), subarachnoid bleed, brain abscess (with rupture)

Rare

Viral meningitis, granulomatous meningitis (cryptococcal, mycobacterial), carcinomatous meningitis, brain tumor

SUBACUTE CENTRAL NERVOUS SYSTEM INFECTION SYNDROME

Subacute onset (>24–48 h) of fever, headache, or meningismus, with no or gradual cognitive impairment

Common

Viral meningitis, viral encephalitis, rickettsial infection

Uncommon

Brain abscess, brain tumor, granulomatous meningitis

Rare

Cerebrovascular accident, carcinomatous meningitis

FIGURE 124-1 ■ Cerebrospinal fluid (CSF) flow within the central nervous system. CSF that forms at the choroid plexus of the cerebral ventricles rapidly enters the subarachnoid space at the foramina of Luschka and Magendie. From the cisterna magna, an organized flow of CSF occurs around the convexities of the brain to the arachnoid villi. There are multiple pathways of bidirectional flow around the spinal cord.

The epidemiology of bacterial meningitis in the United States has evolved in the past 20 years due to the widespread use of vaccines active against *Haemophilus influenzae* type B, *Neisseria meningitidis*, and *Streptococcus pneumoniae*.⁹ Simultaneously, the incidence of nosocomial bacterial meningitis caused by increasingly resistant strains of Enterobacteriaceae, *Pseudomonas aeruginosa*, and *Staphylococcus aureus* is increasing.¹⁰ Meningococcal meningitis presents unique public health and infection control challenges. This diagnosis is suggested by the presence of a petechial or purpuric rash; however, this finding is neither sensitive nor specific.¹¹ To prevent secondary cases among healthcare workers, all patients with presumed bacterial meningitis should initially be placed in isolation to prevent the spread of infection by droplet transmission.

BOX 124-2

Routes by Which Bacteria May Enter the Subarachnoid Space

VASCULAR (BLOOD-BRAIN BARRIER)

Mostly likely pathogens: pneumococci, meningococci, *Listeria*, *Escherichia coli* (neonates), group B streptococci (neonates), *Haemophilus influenzae*

Choroid plexus: may be common site of invasion for *H. influenzae*

Meningeal blood vessels: throughout the subarachnoid space; may be usual route for pneumococci

Arachnoid villi: possible route of invasion, located between the sagittal sinus and subarachnoid space

TRANSDURAL

Most likely pathogens: pneumococci, gram-negative enteric bacilli, staphylococci (including coagulase-negative), *H. influenzae*

Surgery: including ventriculoatrial or ventriculoperitoneal shunts

Trauma: especially when cribriform plate or petrous bone is fractured

Parameningeal infective focus: including sinusitis, mastoiditis, otitis, or osteomyelitis; emissary veins may serve as conduit

Congenital defects: including myelomeningocele and spinal dermal sinus

TRANSPARENCHYMAL

Mostly likely pathogens: anaerobic bacteria, enteric gram-negative bacilli

Occurs when brain abscess ruptures directly into ventricles or subarachnoid space

FIGURE 124-2 ■ This diagram of the potential and actual spaces between the layers of the meninges shows the relationship of blood vessels and nerve roots to the subarachnoid space.

Clinical Manifestations**Bacterial Meningitis**

Bacterial meningitis is a medical emergency, and patients with complications such as seizures or decreased level of consciousness are best managed in the intensive care setting.¹² The initial manifestations may be subtle, with a low-grade headache, nausea, and fever. However, once meningeal signs and symptoms (vomiting, severe headache, and stiff neck) develop, the clinical course is often dramatic. The classic clinical triad associated with bacterial meningitis (fever, neck stiffness, and altered mental status) is present in only 44% of cases.¹³ The signs of meningeal inflammation, including nuchal rigidity, Kernig's sign, or Brudzinski's sign, are neither sensitive nor specific for bacterial meningitis.¹⁴ A purpuric skin eruption is suggestive of meningococcal infections; however, skin lesions may be absent at the time of presentation.¹¹ Bacterial meningitis may present atypically in the elderly or immunocompromised patients, with minimal focal findings.^{15,16} In addition, these populations have a higher incidence of noninfectious conditions that may mimic acute meningitis (e.g., subarachnoid bleeding and malignancies involving the CNS) complicating the initial evaluation.

The diagnosis of meningitis is confirmed through the evaluation of CSF, assuming that there is no contraindication to lumbar puncture

TABLE 124-1 Empiric Antimicrobial Therapy for Adult Patients with Presumed Bacterial Meningitis

| SITE OF ACQUISITION | PREDISPOSITION | ORGANISM(S) | ANTIMICROBIAL AGENT(S) |
|---------------------|-------------------|--|--|
| COMMUNITY | Age 16-50 years | <i>Streptococcus pneumoniae</i> <i>Neisseria meningitidis</i> | Vancomycin plus 3rd-generation cephalosporin* |
| | T-cell deficiency | <i>S. pneumoniae</i> , <i>N. meningitidis</i> <i>Listeria monocytogenes</i> | Vancomycin plus 3rd-generation cephalosporin* plus ampicillin |
| | Age > 50 years | <i>S. pneumoniae</i> , <i>N. meningitidis</i> <i>L. monocytogenes</i> | Vancomycin plus 3rd-generation cephalosporin* plus ampicillin |
| | | Staphylococcal species Gram-negative bacilli (including <i>Pseudomonas aeruginosa</i>) | Vancomycin plus 4th-generation cephalosporin† or meropenem |
| NOSOCOMIAL | | | |

*Ceftriaxone or cefotaxime.

†Cefepime, ceftazidime.

(see below). Prompt transportation and processing of CSF is important to maximize specimen integrity as concentrations of neutrophils degrade by up to 50% after an hour post lumbar puncture.¹⁷ Findings suggestive of bacterial meningitis include neutrophilic pleocytosis, low glucose, and elevated protein levels. A positive Gram stain is diagnostic of bacterial meningitis, with a specificity of more than 99%, although the sensitivity varies based on bacterial burden and the antecedent use of antibiotics.^{18,19}

Management

Delay in antibiotic therapy increases the risk of an adverse outcome or death, particularly when progressive neurologic impairment occurs before receiving therapy.^{8,20} For this reason, guidelines recommend the expedited administration of empiric antibiotics to patients with a presumptive diagnosis of bacterial meningitis.²¹ Even in patients with profoundly abnormal Glasgow Coma Scale scores at presentation, complete recovery may be seen with directed therapy and intensive supportive care.²²

Coupled with the need for emergent treatment is the need for diagnosis. Identification of a pathogen allows a clinician to tailor the antibiotic regimen based on susceptibility patterns and has prognostic and therapeutic implications. However, in some cases, lumbar puncture is unavoidably delayed. When this is the case, antibiotics should be given immediately after peripheral blood cultures are obtained. The yield of CSF culture decreases within as little as 15 minutes following the administration of antibiotics.²³ Nevertheless, the risk of delaying antibiotic treatment outweighs the benefits of making a microbiological diagnosis. Despite the inhibitory effect of prior antibiotics on bacterial culture and Gram stain, the absolute neutrophil count and neutrophilic pleocytosis remain suggestive of bacterial meningitis,^{24,25} and a full course of empiric therapy should be completed if CSF parameters and the clinical presentation are consistent with this diagnosis.

Historically, neuroimaging has been recommended prior to lumbar puncture to exclude the presence of a mass lesion or any other risk factor for brain herniation. Studies have challenged this practice, citing the potential deleterious effect of computed tomography (CT) scan-related delays in the initiation of therapy or the compromising effect of premature sterilization of CSF cultures.^{8,20,23,26} Even among patients with an abnormal CT scan, only a minority of patients have radiographic findings precluding lumbar puncture.²⁷ For this reason, neuroimaging prior to lumbar puncture should be reserved for patients with compromised immune systems (e.g., HIV infection), use of immunosuppressive medications, or organ transplantation), history of an intracranial mass lesion, abnormal level of consciousness, papilledema, or focal neurologic deficits.²¹ In the absence of one of these features, it is generally safe to proceed directly to lumbar puncture, followed by immediate administration of empiric antibiotics.²¹

TABLE 124-2

Antimicrobial Dosages for Central Nervous System Infections

| DRUG | DOSAGE (BY TOTAL BODY WEIGHT) | USUAL DOSAGE (FOR 70-KG ADULT) |
|-------------------------------|--|---------------------------------------|
| Acyclovir | 10 mg/kg IV q 8 h | 700 mg IV q 8 h |
| Ampicillin | 30 mg/kg IV q 4 h | 2 g IV q 4 h |
| Cefotaxime | 30 mg/kg IV q 6 h | 2 g IV q 6 h |
| Ceftazidime | 30 mg/kg IV q 8 h | 2 g IV q 8 h |
| Cefepime | 30 mg/kg IV q 8 h | 2 g IV q 8 h |
| Ceftriaxone | 30 mg/kg IV q 12 h | 2 g IV q 12 h |
| Meropenem | 40 mg/kg IV q 8 h* | 2 g IV q 8 h |
| Metronidazole | 7.5 mg/kg IV q 6 h | 500 mg IV q 6 h |
| Nafcillin | 30 mg/kg IV q 4 h | 2 g IV q 4 h |
| Penicillin G | 60,000-70,000 units/kg IV q 4 h | 4 million units IV q 4 h |
| Tobramycin or gentamicin† | 2-mg/kg IV load, then 1.7 mg/kg q 8 h‡ | 140 mg IV load, then 120 mg IV q 8 h‡ |
| Intrathecal | 0.1 mg/kg/d | 5-10 mg/d |
| Intraventricular | 0.1 mg/kg/d | 5-10 mg/d |
| Trimethoprim-sulfamethoxazole | 5 mg/kg IV q 6 h | 350 mg IV q 6 h§ |
| Vancomycin | 15 mg/kg IV q 6 h | 500 mg IV q 6 h‡ or 1 g IV q 12 h |

*Pediatric dosage. Adults should receive usual dosage.

†Regardless of which aminoglycoside is used, only preservative-free preparations should be used.

‡Adjust dosage based on serum levels, with goal trough 15-20 mcg/mL.

§Dosage indicates trimethoprim component.

Antibiotics

The choice of empiric antibiotics is based on the assessment of the most likely causative agents. Recommendations for empiric therapy are listed in Table 124-1, with dosages commonly used for the treatment of CNS infections listed in Table 124-2.^{21,28} Pneumococci and meningococci remain the most common causes of community-acquired meningitis in immunocompetent adults younger than 50 years.^{28,29} Strains of *S. pneumoniae* that are increasingly resistant to penicillin have emerged as important pathogens; however, many isolates remain sensitive to third-generation cephalosporins, and all are susceptible to vancomycin.³⁰

Antimicrobial therapy should be directed against the most common causes of bacterial meningitis. In the absence of a positive CSF Gram

stain, initial empiric therapy for adults with community-acquired meningitis should include a third-generation cephalosporin such as cefotaxime or ceftriaxone, in combination with vancomycin. Vancomycin should never be used alone as initial therapy because of its marginal CNS penetration and lack of activity against gram-negative organisms. Empiric therapy for *Listeria monocytogenes* should be added for adults aged 50 years or older, patients with T-cell immunocompromise (e.g., on chronic steroid therapy), pregnant women, or patients with significant use of alcohol.^{21,28} If the CSF Gram stain shows gram-positive rods suggestive of *Listeria*, intravenous (IV) gentamicin should be given in addition to ampicillin. For patients intolerant to penicillins, trimethoprim-sulfamethoxazole is an acceptable alternative for treatment of *Listeria* meningitis.

In contrast to community-acquired meningitis, organisms causing nosocomial meningitis reflect the highly resistant strains endemic to the hospital. Empiric therapy for patients suspected to have nosocomial meningitis must therefore be directed against staphylococcal species (both coagulase-positive and -negative strains) and multidrug-resistant strains of gram-negative bacilli, including *P. aeruginosa* and *Acinetobacter baumannii*. Empiric therapy in this population should therefore include vancomycin in addition to an antipseudomonal cephalosporin (ceftazidime or cefepime) or an antipseudomonal carbapenem. Imipenem is active against *Pseudomonas* and achieves therapeutic levels in the CSF; however, because this agent lowers the seizure threshold, it is relatively contraindicated for meningitis. Meropenem, a related carbapenem, is less epileptogenic and is therefore preferred for this indication.³¹

Initial antibiotic choices can be refined when sensitivity patterns become available, typically in 2 to 3 days. The duration of therapy in bacterial meningitis varies with the pathogen and clinical response. Although there have been few randomized studies evaluating the optimal duration of therapy, 7 days of treatment for *H. influenzae* and *N. meningitidis* meningitis is typically sufficient,³² whereas *S. pneumoniae* requires 10 to 14 days of therapy.^{21,33} Adults with pneumococcal meningitis may have predisposing infections including pneumonia, sinusitis, otitis, or rarely, endocarditis, in which case prolonged therapy with bactericidal antibiotics is indicated.

Abnormalities of the CSF (e.g., pleocytosis and elevated protein) may persist for days to weeks following the eradication of infection. The resolution of infectious signs and symptoms (e.g., fever, meningismus, and leukocytosis) should serve as adequate evidence of successful therapy. In a patient who fails to respond to 48–72 hours of empiric therapy, lumbar puncture may be repeated, and head imaging, preferably an MRI with and without contrast, is indicated. A repeat lumbar puncture is particularly important for detecting clearance of bacteria from the CSF in patients with cephalosporin-resistant pneumococcal meningitis who demonstrate a slow clinical response.³⁴ Patients with culture-negative pyogenic meningitis and suboptimal clinical response should also have repeat lumbar puncture to ensure response to empiric antibiotics. Ongoing or worsening CSF parameters suggest infection with either resistant bacteria or with a pathogen more typically associated with a subacute meningitis syndrome (see Box 124-1).

Corticosteroids

Much of the morbidity from bacterial meningitis is caused by the host inflammatory response. Corticosteroids decrease inflammation, and animal studies have shown an improvement in outcome when corticosteroids are given as adjuvant therapy with antibiotics; whether this holds true in humans is less clear. A Cochrane Database review from 2013 evaluated 25 randomized controlled clinical studies on the effect of adjuvant corticosteroids for bacterial meningitis.³⁵ There was no reduction in overall mortality; however, there was a significant decrease in mortality among the subgroup of patients infected with *S. pneumoniae* meningitis. Administration of steroids was associated with a lower incidence of hearing loss and neurologic sequelae as well. Treatment guidelines recommend adjuvant dexamethasone (0.15 mg/kg IV every 6 hours for 2–4 days) given concomitantly with the first dose of

FIGURE 124-3 ■ Extremities—hands (A) and foot (B)—of a 14-year-old boy observed by two physicians as his petechial rash progressed to “bruises” (purpura fulminans). Purpura were not recognized as the hallmarks of *Neisseria meningitidis*-induced sepsis. In addition to the loss of extremities from the necrotizing vasculitis of meningococcemia, the patient rapidly developed signs and symptoms characteristic of the acute meningitis syndrome.

antibiotics for adult patients with suspected or proven pneumococcal meningitis.²¹ Whether steroids are beneficial for other causes of bacterial meningitis remains unclear.

Complications

Complications specific to meningococcal meningitis include purpura fulminans and necrotizing vasculitis leading to skin necrosis and digital gangrene (Fig. 124-3). Nonspecific complications associated with meningococcal as well as other forms of meningitis include adrenal insufficiency due to infarction (Waterhouse-Friderichsen syndrome), renal failure (due to acute tubular necrosis in the setting of hypotension), deafness, hydrocephalus, seizures, and cognitive impairment.

Other Causes of Meningitis

Other organisms including viruses, fastidious bacteria (e.g., *Rickettsia rickettsii*, *Treponema pallidum*), fungi (e.g., *Cryptococcus*), or mycobacteria may also infect the meninges (see Box 124-1). These organisms are often classified as causes of aseptic meningitis to differentiate them from the more fulminant syndrome of bacterial meningitis. In contrast to acute bacterial meningitis, patients with other forms of meningitis are less likely to require admission to the intensive care unit, and in the case of viral meningitis, usually improve spontaneously without antimicrobial therapy.

Differentiating bacterial and nonbacterial etiologies of meningitis may be challenging at the time of presentation, and laboratory data play an important role in making this distinction. Peripheral blood leukocytosis ($>10,000/\text{mm}^3$), CSF white blood cell counts over $1000/\text{mm}^3$, CSF protein concentration over 100 mg/dL , and CSF glucose concentrations below 40 mg/dL favor a bacterial cause. Patients with

these findings should be given empiric antibiotics until a specific diagnosis is made or bacterial cultures return negative. A lymphocytic predominance in the CSF, particularly in the absence of prior antibiotic therapy, argues against a bacterial etiology. Several models incorporating these variables have been developed to predict the likelihood of bacterial meningitis, although these have been best studied in pediatric patients.¹⁴ The measurement of CSF lactate levels has been shown to discriminate bacterial and aseptic meningitis; however, the sensitivity is decreased with prior receipt of antibiotics.³⁶⁻³⁸ Clinical judgment supersedes results from prediction models or biomarkers, particularly given the possibility of a fatal outcome when antibiotic therapy is deferred.

Viruses are the most common cause of aseptic meningitis, with enteroviruses predominating.^{33,39} Other viral causes of meningitis include arboviruses (including West Nile virus), herpesviruses (especially herpes simplex virus [HSV] type 2, which when recurrent is often referred to as *Mollaret's meningitis*), acute HIV infection, and lymphocytic choriomeningitis virus. Viral meningitis is typically a self-limited syndrome and does not require treatment. Laboratory testing may be useful if there is diagnostic uncertainty or to aid in epidemiologic evaluations.

Other causes of culture-negative meningitis may be more aggressive or require directed therapy. These include tickborne infections (such as with *Borrelia*, *Ehrlichia*, or *Rickettsia*), secondary syphilis, mycobacterial or fungal infections, irritation from a parameningeal focus, or partially treated bacterial infections. In these cases, additional diagnostic studies are indicated but should be individualized based on epidemiologic risk factors and clinical findings. Despite intensive diagnostic testing, a pathogen is identified in only two-thirds of patients with subacute meningitis syndrome.³³

BRAIN ABSCESS

A pyogenic brain abscess is a localized suppurative infection of the brain parenchymal tissue and may be caused by infection with bacteria, fungi, mycobacteria, or parasites. Differentiating a brain abscess from other CNS infections or brain tumors may be challenging as there is significant overlap in the clinical and radiologic presentations (Table 124-3). Optimal treatment often requires biopsy to identify the causative organism and obtain susceptibility testing. Even with a combined medical and surgical approach, mortality is significant. Rapid progression of symptoms and impaired mental status at presentation are predictors of an adverse outcome, with rupture of the abscess into the ventricles associated with significant mortality.⁴⁰

Pathophysiology

A brain abscess begins as a localized area of parenchymal infection (cerebritis) that evolves to necrosis and frank suppuration. As cerebritis progresses, a capsule-like hyperemic zone surrounding the area of inflammation develops. In time, liquefactive necrosis leads to abscess formation, with the capsule typically appearing as a ring-enhancing lesion on contrast MRI. In relatively avascular areas such as the cerebral white matter of the brain, capsule formation is delayed, and these sites have higher rates of spontaneous rupture.

Brain abscesses arise through a number of different mechanisms. The most frequent cause is the extension of infection from a contiguous focus (middle ear, mastoids, or sinuses). In approximately one-third of cases, seeding arises through hematogenous spread, and microabscesses typically develop in the distribution of the middle cerebral artery.⁴¹ Filtration of bacteria by the pulmonary vasculature provides some protection for the brain from hematogenous seeding. Therefore, when cardiac shunts or pulmonary arteriovenous fistulae are present, the risk of brain abscess is increased. In patients with endocarditis, multiple microabscesses are often detected clinically and on MRI. Direct inoculation may occur following neurosurgery or intracranial trauma.⁴² In approximately 20% of patients, no obvious source of infection is identified.^{43,44}

The pathogens causing brain abscesses differ according to the route of infection. Abscesses that arise from contiguous sites are frequently polymicrobial. In contrast, brain abscesses associated with hematogenous spread are usually due to a single pathogen. Infections following neurosurgery reflect nosocomial flora and often include multidrug-resistant organisms such as methicillin-resistant *S. aureus* (MRSA) or *Acinetobacter*. The bacteria most often isolated from brain abscesses include Enterobacteriaceae, streptococci, staphylococci, and pneumococci.⁴¹ Fastidious bacteria such as *Nocardia*, fungi such as *Aspergillus*, and even protozoa such as *Toxoplasma* can also be etiologic agents, particularly in immunosuppressed patients.

Clinical Manifestations

The signs and symptoms of a brain abscess relate to variations in location, size, and rapidity of development. At one extreme, the course may span weeks, with few constitutional symptoms. In this setting, signs and symptoms of a space-occupying lesion predominate, and the neoplasm itself is often the primary diagnostic concern. In contrast, a previously asymptomatic brain abscess may rupture into the subarachnoid space, causing death within hours. The differential diagnosis in

TABLE 124-3 Differential Diagnosis of Central Nervous System Infection and Tumor

| | BRAIN ABSCESS | BACTERIAL MENINGITIS | HERPETIC ENCEPHALITIS | BRAIN TUMOR |
|-----------------------------|---------------------|----------------------|-----------------------|------------------|
| HISTORY | | | | |
| Headache | Severe, often focal | Severe, generalized | Mild to severe | Absent to severe |
| Focal defect | Often | Occasional | Occasional | Often |
| Progression | Days to weeks | Hours to days | Days | Days to months |
| PHYSICAL EXAMINATION | | | | |
| Fever | Variable | >90% | >90% | Rare |
| Early focal signs | Often | Occasional | Occasional | Often |
| Pressure signs | Often | Rare | Occasional | Often |
| Extra-CNS infection | Often | Often | No | No |

| Ring effect/onset | Often/late† | No | No | Often/early |

*May be negative or nonspecific during first 48 hours of illness.

†Development of abscess wall may be delayed by steroid therapy.

CT, computed tomography; MRI, magnetic resonance imaging.

this setting includes an acute cerebrovascular event and pyogenic meningitis. However, brain abscesses usually progress subacutely over 7 to 14 days, which is temporally atypical for malignancy and inconsistent with stroke. The most common symptom is headache, which is present in approximately 70% of cases. Other signs and symptoms are less common and include fever (53%), focal neurologic deficits (48%), nausea or vomiting (47%), altered mentation (43%), papilledema (35%), nuchal rigidity (32%) and seizures (25%), and focal neurologic signs (48%).^{43,44} Notably, fever may be absent in as many as 50% of cases, which may lead to a missed or delayed diagnosis. CSF findings are often nonspecific and may be normal in approximately 15% of cases. Lumbar puncture may be contraindicated if there is clinical or radiographic evidence of increased intracranial pressure, given the risk of herniation.

Imaging

Neuroimaging plays a role in both diagnosis and in monitoring response to therapy. Maturation of a brain abscess is associated with encapsulation, and this is visualized as ring enhancement on CT or MRI.⁴⁵ MRI is superior to CT in assessing brain abscesses as the latter may miss small lesions or those localized to the brainstem or cerebellum. Misinterpretation can occur, particularly when the abscess is in the white matter, where decreased vascularity may result in delayed encapsulation with minimal ring enhancement. Similarly, steroid therapy may decrease local inflammation, resulting in the resolution of the ring enhancement. Furthermore, ring enhancement is not specific for bacterial abscesses and may be seen with other infections or brain tumors. Diffusion-weighted imaging is useful for differentiation of a brain abscess from other cystic brain lesions.⁴⁶ Ring-enhancing neoplasms often exhibit facilitated diffusion in the central, non-enhancing area, while abscesses typically demonstrate diffusion restriction.⁴⁵ When differentiating abscess from other pathologies, diffusion-weighted imaging has a sensitivity of 72% to 95% and a reported specificity of 96% to 100%.^{47,48}

Management

In general, a combination approach of antimicrobials coupled with surgical drainage remains the standard approach for the management of pyogenic brain abscesses. The choice of antimicrobials should be guided by culture results, given the diversity of potential pathogens and the need for prolonged therapy (e.g., 6–8 weeks). Because of the difficulty in achieving therapeutic concentrations of antibiotics across the blood-brain barrier, CNS penetration should be considered when selecting an agent. Empiric therapy should be guided by the most likely microbiology based on origin of the infection. In cases in which the source is unknown or a metastatic spread from a distant focus is likely, empiric therapy with vancomycin, metronidazole, and a third-generation cephalosporin is suggested.⁴⁴ An antipseudomonal cephalosporin should be substituted for postneurosurgical infections or for an abscess arising from an otogenic site. Meropenem may be substituted for cephalosporins and metronidazole when there is a contraindication to one of these agents.

Neurosurgical aspiration is invaluable in identifying specific pathogens, and sensitivity testing is crucial for narrowing therapy. Use of stereotactic biopsy allows minimally invasive drainage for both diagnostic and therapeutic purposes. Fungal and mycobacterial cultures should be obtained on all aspirates. Positive cultures from blood or extra-CNS suppurative foci can occasionally establish a presumptive etiologic agent. Ancillary testing for a culture-negative brain abscess includes HIV serology, serum cryptococcal antigen, and toxoplasma titers.

Medical management without drainage may be necessary when the lesion is inaccessible or surgical intervention poses unacceptable risks. However, open or stereotactic drainage is indicated when deterioration from increased intracranial pressure occurs or there is no improvement on medical therapy.⁴⁴ Patients treated without drainage

may require a longer duration (e.g., 12 weeks) of parenteral antibiotics and should be followed closely for clinical and radiographic improvement. Steroids should be reserved for cases in which significant edema is present.

ENCEPHALITIS

Encephalitis is inflammation of the brain parenchyma accompanied by neurologic dysfunction.⁴⁹ Clinical findings include altered mental status (such as disorientation, confusion, and behavioral and cognitive changes), seizures, fever, and focal neurologic signs. The worldwide incidence of encephalitis is estimated at 0.07 to 12.6 cases/100,000 persons,⁵⁰ with mortality in the range of 7% to 18% and severe disability reported in approximately half of all survivors.^{51–53}

Encephalitis presents a diagnostic challenge to the clinician, and a specific etiology is only identified in approximately 50% of all cases.⁵⁴ A myriad of causes may lead to encephalitis, including direct parenchymal infection, postinfectious syndromes such as acute disseminated encephalomyelitis (ADEM) and other immune-mediated etiologies such as neuronal cell surface and synaptic peptide specific autoantibodies (most commonly anti-N-methyl-D-aspartate receptor [NMDAR] autoantibody encephalitis), neuro-Behçet, and others.⁵⁵

Infection is the most common cause of encephalitis and constitutes approximately 50% of identifiable etiologies.⁵⁵ Among the infectious causes of encephalitis, viral infections are the most common. HSV-1 is the single most common cause of sporadic encephalitis worldwide; this pathogen is of particular importance as specific treatment is available. Varicella zoster virus (VZV) is another important cause of encephalitis that is associated with high mortality and treated similarly to HSV. In the United States, West Nile virus neuroinvasive disease is the leading cause of epidemic encephalitis during the summer and early fall. Among the immune-mediated etiologies, we will discuss postinfectious encephalitis such as ADEM and antibody-mediated encephalitis such as anti-GQ1b autoantibody syndrome (eponymously known as Fisher-Bickerstaff encephalitis) and anti-NMDAR encephalitis and will briefly address other antibody-mediated encephalitis.

Infectious Encephalitis

Pathophysiology

The blood-brain and brain-CSF barriers help protect the CNS from the free diffusion of potentially harmful biological and chemical agents.⁵⁶ Most vascular endothelial cells in the CNS are sealed by tight junctions and are unfenestrated. These contribute to the protection afforded by the basement membrane, which functions as an acellular barrier to CNS penetration. Within the CNS, astrocytic foot processes form a dense basal lamina surrounding the brain and spinal cord that contributes to the blood-brain barrier.⁵⁷ Juxtavascular microglial cells and perivascular macrophages within the brain parenchyma surveil the perivascular spaces. Nonfenestrated vascular endothelial cells in the meninges form the brain-CSF barrier. In the choroid plexus, endothelial cells are fenestrated but supported by a second layer of epithelial cells.

Inhaled viruses such as VZV or measles and ingested viruses such as enteroviruses penetrate the mucosal membranes and establish infection in the local lymphoid tissue. Viruses that are inoculated into subcutaneous tissue (e.g., arboviruses) are transported by Langerhans cells to the draining lymph nodes. From the secondary lymphoid tissues, the viruses are shed into the bloodstream and thereby disseminate. Many viruses (including West Nile virus, human T-lymphotropic virus type-1 [HTLV1]), and some bacteria such as *R. rickettsii*, have been shown to directly infect microvascular endothelial cells in vitro.^{58,59} Some viruses are capable of entering vascular endothelial cells by binding to endothelial cell-expressed molecules—for example, HTLV1 can utilize glucose transporter 1 in order to enter the endothelial cell.⁵⁸ Once within the endothelial cell, some agents can alter cellular physiology (e.g. promoting chemokine expression and

altering expression of adhesion molecules), leading to increased vascular permeability and allowing the agent to bypass the first layer of CNS protection.⁵⁷

While the brain is protected by both the blood-brain and brain-CSF barriers, many neurotropic infectious agents have developed mechanisms for gaining entry into the CNS.⁶⁰ Infection of host leukocytes, which are capable of entering the CNS, can serve as a “Trojan horse” neuroinvasive mechanism for viruses such as HIV.⁶¹ Another means of entry is direct neuronal invasion through peripheral nerves.⁶² Rabies virus and some enteroviruses, such as poliovirus, are examples of agents that reach the CNS through this mechanism. Poliovirus initially infects mucosal epithelial cells before gaining access to the CNS via retrograde transport in motor neurons,⁶³ while rabies infects epithelial cells and myocytes at the site of inoculation before gaining access to the nervous system. Once in the motor neurons, rabies virus is transported to the CNS by retrograde axonal transport and through synapses until it reaches the CNS.⁶⁴ HSV-1 infects keratinocytes before entering peripheral sensory nerves and may also gain access to the CNS through olfactory sensory neurons (as may several other viruses).⁶⁵

Individual infectious agents demonstrate variable affinities for different anatomic areas of the CNS. Those with a tropism for the meninges cause meningitis, while those capable of infecting the brain parenchyma can cause meningoencephalitis or encephalitis. Many agents can affect the spinal cord, causing myelitis (discussed below) as well. In older children and adults, HSV-1 characteristically causes temporal lobe encephalitis, whereas HSV-2 more typically causes meningitis. A number of infectious agents have a tropism for the brainstem and can cause a syndrome of brainstem encephalitis. Findings of brainstem encephalitis include cranial nerve palsies, crossed hemiparesis (ipsilateral face/contralateral body from corticospinal tract lesions) or anesthesia (medial lemniscus or spinothalamic tracts), ataxia (cerebellum/cerebellar peduncles), decreased alertness (reticular activating system in the pons), and unusual symptoms such as recalcitrant nausea/vomiting (area postrema). Infectious etiologies that have been associated with brainstem encephalitis include *L. monocytogenes*,⁶⁶ tuberculosis, Whipple's disease,⁶⁷ herpes group viruses,^{68,69} enteroviruses (particularly enterovirus 71), and flaviviruses (especially Japanese encephalitis virus and West Nile virus). There are a number of immune-mediated causes of brainstem encephalitis as well, such as neuro-Behçet, neuro-lupus, neuro-Sjögren, neuro-sarcoidosis, multiple sclerosis, neuromyelitis optica (NMO), chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids, Fisher-Bickerstaff encephalitis, and others.⁷⁰

Clinical Manifestations

In the approach to assessing a patient with possible encephalitis, it is important to first distinguish between encephalitis and encephalopathy without brain inflammation. Encephalopathy without inflammation can result from a number of etiologies—for example, metabolic derangements (hypoglycemia, hypoxia, electrolyte disturbances, renal, and liver disease) and toxin exposure (alcohol, illicit drugs, prescription medications, and environmental contaminants). A clinical case definition for encephalitis that has been proposed by an international working group⁴⁹ includes a major criterion of altered mental status for longer than 24 hours and at least two of the following: fever, seizures not attributable to a previously identified seizure disorder, new focal neurologic findings, CSF white cell count more than 5/mm³, and abnormalities on neuroimaging or EEG. This definition was designed for research and epidemiologic purposes but also provides case definition for a clinician.

Management

The history and physical examination are critically important in the diagnostic evaluation of the patient with encephalitis. Particular attention should be given to recent infectious symptoms, risk factors for tuberculosis or other infectious agents, unusual insect or toxin exposures, travel, rash, and neuropsychiatric symptoms. Full neurologic

and general examinations are important in guiding the diagnostic approach. Given the broad differential diagnosis, a diagnostic algorithm has been proposed that emphasizes the most common causes, those that benefit from targeted therapies, and those that pose a particular public health threat.^{49,71} Once a clinical diagnosis of encephalitis is suspected, empiric therapy with antiviral agents should be initiated while the diagnostic evaluation is under way.

Serum laboratory studies that should be obtained on all adults include CBC with differential, electrolytes, measures of renal and liver function, blood cultures, HIV testing, and treponemal testing. *Mycoplasma pneumoniae* IgM and IgG, EBV serologies (VCA IgG and IgM and EBNA IgG) should be obtained in children with encephalitis. Serum should be reserved from presentation, and convalescent serum should be collected 10 to 14 days later for paired antibody testing as indicated. Lumbar puncture should be obtained in all patients with encephalitis with opening pressure, cell count and differential, protein, glucose, Gram stain, oligoclonal bands, IgG index, bacterial cultures, HSV-1/2 PCR, VZV PCR and if available, VZV IgG and IgM, enterovirus PCR, cryptococcal antigen, or India ink staining and VDRL.

Neuroimaging, preferably MRI with and without contrast, should be obtained in all patients and may reveal an abscess, meningeal enhancement, limbic edema, ADEM, or other important diagnostic clues. EEG should be obtained in all patients with encephalitis and continuous EEG monitoring may be warranted in some patients as nonconvulsive status epilepticus is a common mimic and complication of encephalitis.⁷²

Patients with depressed consciousness, increased intracranial pressure, or seizures are best managed in an intensive care setting. All patients with encephalitis should be treated with IV acyclovir pending CSF PCR result for HSV. Empiric antibiotics should be given if there is concern for meningoencephalitis or a bacterial etiology such as *Listeria* rhomboencephalitis. Anticonvulsant therapy should be initiated in patients with clinical or subclinical seizures but not prophylactically. With the exception of encephalitis due to herpes group viruses and a few other agents (see below), the management of most viral encephalitides revolves around supportive care including control of seizures.⁷³

Herpesvirus Encephalitis

Herpes Simplex Virus Encephalitis

HSV-1 and -2 are two of eight human herpesviruses (HHVs), which also include VZV (HHV-3), Epstein-Barr virus (HHV-4), cytomegalovirus (HHV-5), HHV-6, HHV-7, and HHV-8. HSV-1 and -2 infections are common, with HSV-1 seropositivity at 80% to 90% worldwide.⁷⁴ HSV-1 is the most common cause of sporadic encephalitis in the United States, responsible for approximately 90% of HSV encephalitis in adults and children (with HSV-2 responsible for the remainder).⁷⁵ The mortality due to untreated HSV-1 encephalitis is roughly about 70%, and neurologic sequelae are almost universal in the absence of treatment.⁷⁵ However, timely administration of acyclovir has been shown to significantly improve survival and improve outcomes, particularly when initiated early in the course of infection.^{76,77}

HSV-1 encephalitis may be due to reactivation of the dormant virus or may occur in the setting of primary infection.⁷⁸ The virus has a tropism for the orbitofrontal and temporal lobes; however, no combination of clinical, laboratory, or radiographic findings is sufficiently sensitive to confirm the diagnosis, and an empiric acyclovir therapy should be given to all patients until all definitive diagnostic studies are completed.⁷³

Signs and symptoms typical of HSV-1 encephalitis reflect virus replication and inflammation in the medial temporal and orbitofrontal lobes and include personality change, aphasia, and seizures, in addition to other features of encephalitis.⁷⁹ Progressive temporal lobe edema can lead to uncal herniation with mydriasis (usually ipsilateral), which can progress to further herniation and death. When HSV-2 affects the CNS, it primarily causes meningitis, which may be recurrent

(Mollaret's meningitis) but may rarely cause encephalitis as well. HSV-2 can also cause brainstem encephalitis and myelitis.

The MRI is abnormal in most cases and may disclose unilateral or bilateral abnormalities within the mesial temporal and orbitofrontal lobes, the two most commonly affected structures.⁸⁰ Diffusion-weighted imaging may be more sensitive for HSV-1 encephalitis, particularly early in the course of the illness.⁸⁰ In one recent study, EEG was significantly more likely to demonstrate periodic discharges or focal slowing in frontotemporal leads in patients with HSV encephalitis compared to those with encephalitis from other causes.⁸¹

The CSF exhibits lymphocytic pleocytosis in over 90% of patients but may appear normal early in the course and is nonspecific. The CSF protein is usually elevated, and glucose level is generally normal. CSF PCR for HSV-1 and -2 DNA remains the diagnostic test of choice with a high sensitivity (96%) and specificity (99%).^{82,83} Empiric acyclovir therapy can usually be discontinued if the PCR result is negative, although there have been reports of false negative results early in the course of the disease; therefore, if the clinical suspicion for HSV encephalitis is high, repeat lumbar puncture and PCR for HSV should be performed after 48 hours while empiric acyclovir therapy is continued.⁸⁴

IV acyclovir 10 mg/kg every 8 hours is the treatment of choice for HSV-1 and -2 encephalitis and should be continued for a minimum of 14 to 21 days.⁸⁵ Caution should be used in renal impairment. The safety and efficacy of adjunctive corticosteroids have not been rigorously investigated, and these are typically reserved for use in patients with significant edema or a mass effect.⁸⁶ Cognitive deficits and seizures are significant sequelae among survivors. A recent trial of long-term valacyclovir after standard treatment for HSV encephalitis, while well tolerated, did not improve long-term outcomes.⁸⁷

While the illness is typically monophasic, 12% to 27% of patients will suffer an apparent clinical relapse days to months after the initial illness. Most affected are children who develop encephalopathy with choreoathetosis,⁸⁸ but many adults experience apparent relapse as well.⁸⁹ Recent evidence indicates that many of these patients have developed autoantibodies targeting neural peptides that are responsible for the clinical relapse.⁹⁰ HSV has been associated with a number of autoantibodies, including NMDA receptor, dopamine-2 receptor,⁹¹ and voltage-gated calcium channel⁹² autoantibodies as well as antibodies to unidentified neuronal antigens.⁹³ Patients with clinical relapse after viral encephalitis should be evaluated for autoimmune antibodies and consideration given to empiric immunosuppression once infectious etiologies have been excluded.

Varicella Zoster Virus Encephalitis

VZV is an important cause of encephalitis and was responsible for 5% of cases of encephalitis in one recent study, with a high case-fatality rate.⁵¹ VZV can also cause meningitis, myelitis, and vasculopathy that may lead to multifocal ischemic infarction, which may be recurrent (VZV has also been implicated in the pathogenesis of giant cell arteritis).⁹⁴ The diagnosis is confirmed by demonstrating VZV PCR positivity or elevated VZV IgG levels in the CSF. Treatment is similar to that for HSV encephalitis and consists of IV acyclovir for 10 to 14 days. Cutaneous zoster in the setting of encephalitis warrants empiric therapy while diagnostic evaluation is under way.

Immune-Mediated Encephalitides

While viral infections constitute the most commonly identified causes of encephalitis, it is increasingly recognized that immune-mediated encephalitis accounts for a substantial burden of disease and is the second most common cause of encephalitis.^{55,95} In particular, the autoimmune encephalitides associated with antibodies targeting neuronal cell-surface or synaptic antigens warrant discussion. In 2005, six patients with encephalitis were reported, all of whom had unidentified neural cell surface antibodies and improved with immunotherapy and/or tumor removal.⁹⁶ This small case series ushered in the study and characterization of a number of autoimmune antibody syndromes, a

growing area of interest that has had a significant impact in the fields of medicine, neurology, and psychiatry and has profoundly impacted many patients' lives. Since the discovery of anti-NMDAR encephalitis in 2007,⁹⁷ one to two novel pathogenic autoantibody syndromes have been identified yearly. Among these, anti-NMDAR encephalitis is the most common and is relatively frequently identified as a cause of encephalitis.⁵¹ In one large-scale study, anti-NMDAR encephalitis was the most commonly identified cause of encephalitis in patients who were 30 years or younger.⁹⁵

Pathophysiology

Binding of autoantibodies to their target extracellular epitopes on neural cell surface or synaptic proteins can lead to alteration of the structure or function of the target antigen.⁹⁸ Anti-NMDAR encephalitis is the best studied of the autoimmune encephalitides. The NMDAR is localized to the postsynaptic membrane and clustered at the postsynaptic density. In cultured neurons, the binding of patient IgG antibodies to the GluN1 subunit of the NMDAR leads to selective crosslinking and internalization of the NMDAR in a titer-dependent, reversible manner.^{99,100} Anti-GABA_BR and anti-AMPA_R antibodies have also been shown to cause selective internalization of their respective receptors in cultured neurons.^{101,102} More recently, Planaguma and colleagues demonstrated *in vivo* pathogenicity of anti-NMDAR antibodies by continuously infusing CSF from patients with anti-NMDAR encephalitis into the ventricles of mice, which caused memory and behavioral deficits.¹⁰³ Hippocampal analysis demonstrated accumulation of bound antibodies over time with a decrease in the number of synaptic NMDARs. Both the clinical and pathologic consequences improved with the cessation of antibody infusion.

Clinical Manifestations

The importance of the clinical history and examination cannot be overstated and there has been a tendency to be overreliant on antibody testing in autoimmune encephalitis (AIE). A recent position paper from experts in the field outlines a clinical approach to AIE.¹⁰⁴ The criteria for possible AIE include subacute, progressive deficits in memory, altered mental status or psychiatric symptoms with new focal CNS findings, unexplained seizures, CSF pleocytosis, or MRI suggesting encephalitis in patients in whom reasonable alternative causes have been excluded. Here we will briefly discuss anti-NMDAR encephalitis, but interested readers are referred to several recently published reviews of immune-mediated encephalitides.¹⁰⁵⁻¹⁰⁸

Anti-NMDAR encephalitis most commonly occurs among young females with a median age of 21 years (0.6-85 years). The syndrome develops over stages with approximately 70% experiencing a viral prodrome consisting of headaches, fevers, vomiting, diarrhea, and/or upper respiratory tract symptoms.¹⁰⁹⁻¹¹¹ Within 2 weeks, behavioral and neuropsychiatric manifestations develop and can easily be misinterpreted as evidence of a primary psychiatric condition. This is followed by a depressed level of consciousness that may alternate with episodes of agitation and catatonia. Dissociative responses such as resistance to eyelid opening and no reaction to noxious stimulation may be observed, similar to findings in pharmacologic NMDAR antagonism such as ketamine.¹¹² In this stage, patients develop a variety of abnormal movements and autonomic dysfunction that may lead to respiratory failure requiring mechanical ventilation.

Seizures are common throughout the illness, and EEG is abnormal in most patients. The extreme delta brush pattern, which consists of 1- to 3-Hz delta activity with superimposed 20- to 30-Hz beta activity, may be observed in 33% of patients and is relatively unique to NMDAR encephalitis.¹¹³ Brain MRI is abnormal in only 23% to 50% of patients and may reveal nonspecific T2 hyperintense lesions in the frontal, parietal, medial temporal, or posterior fossa and occasionally, the basal ganglia.¹¹⁴ A PET scan may demonstrate frontotemporal hypermetabolism with occipital hypometabolism.¹¹⁵ The detection of anti-NMDAR antibodies confirms the diagnosis, and autoantibodies should be sought in both the serum and CSF as 6% to 13% of patients will only have autoantibodies detectable in the CSF, depending on the method

used for antibody detection.¹¹⁶ There is also a risk of false positive results if testing is limited to the serum.¹¹⁷

Management

Management includes immunotherapy and the removal of any underlying antigenic stimulus. With treatment, 70% to 80% of patients with anti-NMDAR encephalitis will attain complete or near-complete recovery, and signs and symptoms of the disease generally abate in reverse order.¹¹⁸ Any mass lesion should be promptly removed, particularly ovarian or testicular masses, as neurologic symptoms often resolve following surgery. A retrospective analysis of 501 patients treated for anti-NMDAR encephalitis provides the most comprehensive data regarding outcomes.¹¹⁹ Treatment varied among patients and included first-line regimens consisting of tumor removal (when present), corticosteroids, IV immunoglobulin, or plasmapheresis and second-line treatment with rituximab (anti-CD20 monoclonal antibody) and/or cyclophosphamide. For patients who received first-line therapy, 53% improved within 4 weeks. Among patients who did not respond to first-line therapy, 57% were given second-line therapy, which was associated with improved outcomes compared to those who were continued on first-line therapy alone. Patients may require hospitalization for months while undergoing evaluation and treatment.

Although no data have demonstrated the superiority of one regimen over another, some authors have suggested first-line therapy with IV immunoglobulin (0.4 g/kg per day for 5 days) and methylprednisolone (1 g/day for 5 days) over plasmapheresis.¹¹¹ If improvement is not noted within 10 days, second-line therapy with rituximab (375 mg/m² every week for 4 weeks) or cyclophosphamide (750 mg/m² monthly for 3 to 6 months) should be considered. There are a few case reports of intrathecal methotrexate in place of cyclophosphamide.¹²⁰ Once substantial clinical improvement is noted, treatment can be discontinued in most patients; however, 20% to 25% of patients (usually those without a teratoma) may relapse, and longer term immunosuppression should be considered in these patients.

Acute Disseminated Encephalomyelitis

Acute disseminated encephalomyelitis (ADEM) is an immune-mediated inflammatory demyelinating disease of the CNS that is generally monophasic and can be difficult to prospectively distinguish from other causes of encephalitis. ADEM can occur in adults but most often affects children, with an annual incidence of 0.07 to 0.6/100,000 people.¹²¹⁻¹²³ ADEM generally presents within 2 to 4 weeks of an infectious illness or, occasionally, vaccination, but antecedent exposure may be absent in 26% of patients.¹²⁴ This observation, combined with data from an animal model of demyelination (experimental autoimmune encephalomyelitis) has led to the postulate that the pathogenesis is related to molecular mimicry in which antigenic epitopes are shared between pathogens or vaccines and host myelin. Alternatively, CNS infection with the subsequent inflammatory cascade may lead to disruption of the blood-brain barrier, exposing CNS antigens to the host immune system, which may lead to breakdown of tolerance.

The syndrome is clinically indistinguishable from encephalitis, with fever, encephalopathy (42%-83%),¹²⁵ headache with or without vomiting (15%-37%), meningeal signs (13%-43%), seizures (4%-48%), focal weakness (17%-77%), ataxia (10%-52%), cranial nerve palsies (11%-48%), and/or visual impairment (7%-23%).^{126,127} CSF analysis may disclose a variable degree of lymphocytic pleocytosis with mildly to moderately elevated protein levels, normal glucose levels, normal Gram stain with sterile cultures, and transient oligoclonal bands in 0% to 29%.¹²⁷

The MRI findings in ADEM typically include multiple large (>1-2 cm) asymmetric T2 and FLAIR hyperintense lesions randomly distributed in the cerebral hemispheres, cerebellum, brainstem, and spinal cord.¹²⁸⁻¹³⁰ Lesions classically involve the white matter but commonly develop in the deep gray matter as well, particularly the thalamus and basal ganglia, where they tend to be more symmetric.¹²⁴ The frequency and patterns of gadolinium enhancement are highly variable in ADEM (8%-100%), depending on the stage of inflammation,

although all lesions tend to be at the same stage at the same time (in contrast to the lesions seen with multiple sclerosis). ADEM is classically a monophasic illness, and signs and symptoms generally resolve over time; however, multiphasic ADEM has been reported. There is no standard treatment for ADEM, and the current suggested therapy is based on level IV evidence. After infectious and other causes of encephalitis have been excluded, most authors suggest high-dose IV methylprednisolone (20-30 mg/kg/day to maximum of 1 g/day) for 3 to 5 days followed by oral prednisone tapered over 4 to 6 weeks.^{127,129,131,132} For patients who are not responding to steroids, IV immunoglobulin has been reported to be successful in several case studies and can be considered. A reasonable regimen is 2 g/kg IV divided into doses given daily over 2 to 5 days (e.g., 0.4 mg/kg given daily for 5 days). In cases of fulminant ADEM unresponsive to steroids, plasma exchange can be considered and has been shown to be effective in aggressive CNS demyelination.¹³³

MYELITIS AND MYELOPATHY

Myelopathy refers to any pathology of the spinal cord with associated neurologic dysfunction and includes noninflammatory etiologies such as nutritional deficiency and malignancy. Myelitis is an inflammatory cause of myelopathy and may occur in isolation (e.g., poliovirus myelitis or herpesvirus myelitis) or coexist with encephalitis as an overlap syndrome (e.g., acute flaccid paralysis associated with West Nile virus encephalomyelitis, progressive encephalomyelitis with rigidity and myoclonus, or ADEM). The differential diagnosis of myelitis includes infectious and immune-mediated etiologies in addition to noninflammatory causes of myelopathy such as vitamin deficiencies (e.g., B12, copper), vascular myelopathies, and neurodegenerative conditions.

The differential diagnosis for myelitis is shown in [Box 124-3](#). Some causes, such as ADEM and other postinfectious myelitides, are monophasic, while others, such as multiple sclerosis, neuromyelitis optica, lupus myelitis (now recognized to be often associated with neuromyelitis optica), and neurosarcoidosis can be progressive and/or relapsing.

A thorough history and neurologic examination are critical for defining the temporal profile and localization. Back or neck pain (especially funicular pain), bowel or bladder dysfunction, saddle anesthesia, and bilateral upper or lower extremity weakness are historic features that suggest a spinal localization. The temporal profile is helpful in determining etiologic probabilities. For example, a hyperacute presentation is suggestive of a vascular or traumatic etiology,

Vascular myelopathy

while an acute-subacute temporal profile suggests inflammatory or infectious etiologies and a subacute-chronic course implies nutritional deficiency or malignancy.

Identifying a spinal level is a key step in localizing a lesion to the spinal cord, and the pattern of localization may assist in determining the etiology (e.g., weakness and loss of pain/temperature with preserved vibration and proprioception in cases of anterior spinal artery occlusion or loss of vibration and proprioception with preserved pain/temperature and motor function in tertiary syphilis). In the acute setting, patients may present with hyporeflexia that can mimic Guillain-Barré syndrome, a finding that can mislead the diagnostician to a peripheral localization. While a localization can usually be identified, none of the features on the examination or history is sufficiently sensitive or specific to differentiate between inflammatory, vascular, or compressive causes. Therefore, all patients with myelitis should be managed as true emergencies utilizing a standardized approach.

The first step in the diagnostic approach to possible myelitis is to exclude extrinsic cord compression that might warrant surgical intervention.¹³⁴ Emergent imaging is indicated if cord compression is suspected as early decompression dramatically improves functional outcomes. The preferred modality is spinal MRI with and without contrast, although CT myelography is a reasonable alternative if MRI is contraindicated. Once compression is excluded, lumbar puncture with cell count and differential, total protein, glucose, Gram stain/cultures, IgG index, and oligoclonal bands should be obtained with an extra sample reserved for future studies. In addition, antiaquaporin-4 autoantibodies, SSA/SSB, ANA, anticardiolipin antibodies, copper, B12, treponemal antibody, CSF varicella zoster PCR and IgG, and enterovirus PCR should be considered. Inflammation of the spinal cord is supported by contrast enhancement on MRI, CSF pleocytosis, or elevated CSF IgG index.

There are four key steps in the management of myelitis: (1) recognition of the syndrome, (2) extinguishing acute inflammation, (3) determining the etiology, and (4) long-term management. While the diagnostic evaluation is under way, high-dose steroids (typically with 1 g IV methylprednisolone daily for 3–7 days) should be given in order to decrease the acute inflammation.¹³⁵

When infectious etiologies are suspected or confirmed, appropriate antimicrobial agents should be given. Patients with longitudinally extensive myelitis associated with lupus may benefit from the addition of cyclophosphamide to corticosteroids and plasma exchange.^{136,137} Those with myelitis as a result of neuromyelitis optica should be treated with steroids and plasma exchange, a regimen associated with improved outcomes.^{138–140} When neurosarcoidosis presents with myelitis, corticosteroids are usually effective,¹⁴¹ and refractory cases may respond to TNF- α antagonism (such as with infliximab).^{142,143} No specific regimen for infliximab in this setting has been validated as only small case series exist, but doses range from 3 to 5 mg/kg, including induction with doses at 0, 2, and 6 weeks and maintenance dosing every 4 to 6 weeks thereafter. Notably, TNF- α antagonism can worsen multiple sclerosis and is contraindicated in these patients.¹⁴⁴ In managing patients with severe myelitis of unknown etiology, consideration should be given to concomitant steroids and plasma exchange, which was associated with improved outcomes in at least one retrospective review.¹³⁷

Myelopathy from B12 deficiency should be treated with 1000 μ g intramuscular B12 daily for a week, weekly for a month, and then monthly thereafter. Depending on the cause of deficiency, some patients can eventually be treated with oral B12.¹⁴⁵ Hypocupremic myeloneuropathy should be treated with oral elemental copper 8 mg by mouth daily for a week, then 6 mg daily for a week, then 4 mg daily for a week, followed by 2 mg daily thereafter.¹⁴⁶ The underlying cause of deficiency should be identified (often associated with excessive zinc consumption, gastrointestinal surgeries, or malabsorption syndromes). Nitrous oxide toxicity may present with subacute-acute myelopathy and has been reported after a single exposure.¹⁴⁷ Nitrous oxide inactivates B12 by oxidizing the cobalt center of the molecule; therefore,

treatment is with vitamin B12. Heroin use may cause an acute myelopathy, the treatment of which is supportive.

Ischemic myelopathy secondary to spinal cord infarction is managed with lumbar drainage and hemodynamic augmentation with vasopressors in order to increase perfusion of the spinal cord.¹⁴⁸ Recent guidelines from the Congress of Neurological Surgeons recommend against the use of steroids in acute spinal cord infarction,¹⁴⁹ unless caused by vasculitis. Physical and occupational therapy are important interventions in the care of all patients with myelopathy. Long-term medical management is contingent upon the etiology of the myelitis.

CENTRAL NERVOUS SYSTEM INFECTION AND THE ACQUIRED IMMUNODEFICIENCY SYNDROME PATIENT

Patients with HIV/AIDS are susceptible to an array of opportunistic infections in addition to the more common causes of CNS infection. Those who present with altered mental status or an abnormal neurologic examination represent a diagnostic challenge. Differentiating baseline neurocognitive dysfunction associated with HIV from neurologic dysfunction related to malignancy or opportunistic infections requires a thoughtful and systematic diagnostic approach to allow rapid and appropriate treatment of what are frequently life-threatening infections.

Pathophysiology

It has long been recognized that opportunistic infections of the CNS are common in patients with HIV, including cryptococcus, toxoplasmosis, and tuberculosis.¹⁵⁰ More recently, the neurocognitive effects of HIV itself have become more widely recognized and are broadly termed *HIV-associated neurocognitive disorders* with HIV-associated dementia reserved for the most severe cases of cognitive dysfunction.¹⁵¹ Before the availability of highly active antiretroviral therapy, it was estimated that 20% to 30% of patients with uncontrolled HIV suffered from HIV-associated dementia.¹⁵² Over 40% of patients with HIV will present with neurologic manifestations, either related to the direct involvement of HIV itself or related to opportunistic infections over the course of their lives.¹⁵⁰ The neuropathogenesis of HIV has recently been reviewed, to which interested readers are referred.¹⁵³ Here we will focus on opportunistic infections associated with HIV.

Clinical Manifestations

The most important factor in approaching a patient with HIV and neurocognitive changes is the degree of immunosuppression of the patient. This framework can be used to establish the most likely etiologies in the differential diagnosis. Patients with CD4 counts higher than 500/ μ L are more likely to present with benign or malignant brain tumors, stroke, and other conditions common to immunocompetent patients. Those with CD4 counts between 200 and 500/ μ L are more likely to present with HIV-associated cognitive and motor disorders, while patients with CD4 counts lower than 200/ μ L are more likely to have CNS mass lesions, HIV-associated malignancy (such as CNS lymphoma), and opportunistic infections.

Management

In approaching a patient with HIV who presents with neurologic manifestations, a systematic approach is important. We recommend imaging prior to lumbar puncture in all patients in whom there is concern for increased intracranial pressure or a mass lesion. A brain MRI with and without gadolinium contrast is the preferred method and can assist in securing the diagnosis.¹⁵⁴ In addition to the standard

diagnostic studies, CSF analysis in HIV/AIDS patients should include cytology, cryptococcal antigen/India ink staining, VDRL (for syphilis), and PCR for herpesviruses, JC virus, and *Mycobacterium tuberculosis*.¹⁵⁵ The clinical manifestations and management of several of the most common CNS infections in patients with HIV are briefly reviewed below.

Toxoplasmosis

An obligate intracellular protozoan, *Toxoplasma gondii* is the most common HIV-associated opportunistic infection of the CNS.¹⁵⁶ It is found in cat feces and undercooked pork, and infection rates in the United States are estimated to be between 15% and 25%.¹⁵⁷ In patients with CD4 counts lower than 100/ μ L, CNS reactivation of chronic toxoplasmosis infection most often presents as acute to subacute encephalitis.¹⁵⁸ Brain MRI with and without gadolinium contrast is more sensitive than CT,¹⁵⁹ but there are no pathognomonic findings.¹⁵⁴ MRI findings suggestive of toxoplasmic encephalitis include multiple nodular or ring-enhancing lesions, usually with extensive surrounding vasogenic edema, with a predilection for the basal ganglia and corticomedullary junction.¹⁶⁰ On noncontrast images, the appearance of lesions is highly variable; they may be iso- or hypointense on T1-weighted images and hypo-, iso-, or hyperintense on T2-weighted sequences. The “eccentric target sign” is an infrequent, but highly specific (95%), finding.¹⁶¹ Most patients with toxoplasmic encephalitis have positive serologies for toxoplasmosis, but their absence does not exclude the infection. PCR of the CSF for toxoplasmosis is highly specific but insensitive and is not universally available. Treatment consists of sulfadiazine, pyrimethamine, and leukovorin (given to prevent pyrimethamine-induced hematologic toxicity). Patients who are unable to take sulfadiazine can be given clindamycin. Maintenance therapy should be given to prevent further episodes of infectious reactivation. Corticosteroids should be reserved for patients with a significant mass effect. Surgical intervention is typically reserved for patients with signs of impending herniation or lack of radiographic response after 2 weeks of empiric therapy for toxoplasmosis, in which case a biopsy to exclude an alternative cause, such as CNS lymphoma, is indicated.

Cryptococcus

Cryptococcus neoformans, an encapsulated budding yeast, is commonly found in soil contaminated by bird feces. Cryptococcal meningitis is the second most common CNS infection in patients with HIV. Cryptococcus can cause meningitis or meningoencephalitis and typically presents as subacute (1–2 weeks) meningitis but can rarely present with fulminant disease progressing to death over several days. A high index of suspicion is warranted in patients with low CD4 counts (especially <100/ μ L). Neuroimaging findings are highly variable and may be normal. Some features that suggest cryptococcal meningoencephalitis include dilated Virchow-Robin spaces, pseudocystic and cystic masses, meningitis, or hydrocephalus.¹⁵⁴ Many patients present with evidence of elevated intracranial pressure (>20 cm H₂O) that is characterized by decreased consciousness, papilledema, and sixth nerve palsy. The CSF classically reveals a low nucleated cell count (<50/ μ L), with a mononuclear predominance, elevated protein, and low glucose levels but is normal in up to 30% of infected patients.^{162,163} The CSF should be tested for the presence of cryptococcal antigen.¹⁶⁴ Opening pressure should be checked in all patients undergoing lumbar puncture as elevated pressure is associated with an increased risk of mortality without treatment. Patients with elevated intracranial pressure should be treated with at least one therapeutic lumbar puncture.¹⁶⁵ Patients with moderately elevated intracranial pressure present with an opening pressure of less than 20 cm H₂O. When symptomatic patients have an extremely high pressure, the pressure target should generally be 50% of the initial value. Daily lumbar puncture may be necessary until normalization/stabilization of pressures, and some patients may require lumbar drains or ventriculoperitoneal shunting. Antifungal therapy includes an

induction phase with liposomal amphotericin B (amphotericin B deoxycholate is an alternative if the liposomal form is unavailable) and flucytosine for at least 2 weeks, followed by consolidation therapy with fluconazole.^{166,167}

Herpesviruses

Immunocompromised patients with herpetic infections of the CNS present a diagnostic challenge, and the index of suspicion should be high in order to avoid missing the diagnosis. Immunocompromised patients with herpes encephalitis are less likely to present with prodromal symptoms or focal neurologic deficits, have more extensive radiographic involvement (often distributed outside the temporal lobes), and have CSF pleocytosis.¹⁶⁸ Even with modern treatment and supportive care, mortality among the immunocompromised is significantly higher than among the immunocompetent, with reported mortalities of 35.7% and 6.7%, respectively. As in immunocompetent patients, acyclovir is the preferred agent.

Cytomegalovirus (CMV) is another herpesvirus that is latent in the majority of the population and may reactivate, most often in immunocompromised persons. CMV can cause encephalitis, retinitis, myelitis, polyradiculopathy, and peripheral neuropathy and is most likely to manifest when the CD4 count is less than 50/ μ L. Findings on MRI are neither sensitive nor specific. MRI may reveal diffuse or focal T2 hyperintense lesions predominantly involving the periventricular white matter and possibly evidence of ventriculoencephalitis, characterized by T2 hyperintense lesions along the ependymal lining of the lateral ventricles that may enhance with the administration of gadolinium.¹⁶⁹ Analysis of the CSF may reveal neutrophilic pleocytosis and elevated protein and low glucose levels, though these findings are variably present.¹⁶⁹ CMV PCR should be obtained from the CSF, and high levels of viral DNA in the proper clinical context confirm the diagnosis, although low levels may be difficult to interpret. There are several treatment regimens in use for neurologic infections with CMV. Most clinicians use a combination of ganciclovir and foscarnet for patients with CNS infection, but patients who are unable to tolerate combination therapy can be treated with either agent alone.

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a life-threatening demyelinating disease of the CNS that results from reactivation of the polyoma JC virus.¹⁷⁰ Primary infection usually occurs in childhood, although one study found that 86% of adults have antibodies to the virus.¹⁷¹ In most patients, the virus remains latent in the kidneys and the lymphoid organs, but in an immunocompromised individual, the virus may reactivate and spread to the CNS where it causes a lytic infection of oligodendrocytes. PML usually manifests with subacute, progressive neurologic deficits including personality change, altered mental status, and focal neurologic deficits referable to the localization of the infection. Seizures may occur in up to 18% of patients and are likely related to cortical or juxtacortical involvement.¹⁷² Most patients with HIV who present with PML have CD4 counts of less than 100 μ L, but PML has been associated with immunosuppression that is related to a number of medications including mycophenolate mofetil,¹⁷³ rituximab,^{174,175} and natalizumab.^{176,177} PML classically affects the white matter, manifesting on MRI as symmetric or asymmetric T1-hypointense/T2-hyperintense lesions that may become confluent.¹⁵⁴ In patients with a profound immunocompromised status,¹⁷⁸ there may be minimal or no enhancement with gadolinium, but in the setting of PML-immune reconstitution inflammatory syndrome or with medications such as natalizumab, contrast enhancement is more common.¹⁷⁹ Viral PCR from the CSF should be obtained when PML is suspected and is highly specific. However, the sensitivity has decreased to 60% in the era of highly active antiretroviral therapy.¹⁸⁰ Consequently, in some cases, brain biopsy may be required to establish the diagnosis. There remains no specific treatment for PML; therefore, treatment is

aimed at restoring immune function. In patients with HIV, initiation or optimization of antiretroviral therapy is the best option and can prolong survival.^{181,182} As the serotonin receptor 5HT_{2a} can serve as a receptor for the virus, the addition of mirtazapine may be beneficial, but evidence is limited to case reports.¹⁸³⁻¹⁸⁵ In patients who develop PML while on natalizumab, the drug should be discontinued immediately and the patient should undergo emergent plasma exchange every other day for five treatments in order to remove natalizumab.¹⁸⁶ PML is associated with a bleak prognosis and is almost uniformly fatal in patients with AIDS.^{187,188}

Central Nervous System Lymphoma

Patients infected with HIV are predisposed to several malignancies including primary CNS lymphoma (PCL),¹⁸⁹ which are strongly linked to Epstein-Barr virus (EBV) infection.¹⁹⁰ PCL can mimic an opportunistic infection, and MRI may be helpful in differentiating the etiology of mass lesions in patients with AIDS. AIDS-related PCL is often associated with a high degree of contrast enhancement, which is typically irregular and inhomogeneous.^{191,192} Lesions that involve the corpus callosum and periventricular or periependymal areas are more likely to represent PCL, while PCL involves the posterior fossa in less than 10% of cases in this population.^{191,193} Among the conditions discussed here, PCL and toxoplasmosis are most likely to cause a mass effect.¹⁹⁴ As there is clinical and radiologic overlap with opportunistic infections, these should be thoroughly evaluated as outlined above with the inclusion of CSF testing for EBV PCR, cytology, and flow cytometry. In the absence of a pathologic diagnosis, empiric corticosteroids should be used with caution as these may decrease the diagnostic yield for CNS lymphoma.

PARADURAL ABSCESS

The epidural space is between the dura and the bony structures of the skull and vertebral column; the subdural space is between the subarachnoid membrane and the dura (see Fig. 124-2). Unlike the subarachnoid space, the paradural tissues are only potential spaces, with the arachnoid membrane and the dura limiting the spread of infection across their surfaces. Although subdural abscesses are more common within the cranium and epidural abscesses are more common within the vertebral column, the causes, pathophysiologies, and therapies are similar. These abscesses usually develop from a contiguous infection, surgery, or trauma.

Cranial Paradural Abscess

In the skull, the epidural tissues are dense and abscess formation is unusual. The subarachnoid membrane is less adherent to the dura, making the subdural space the more likely site of infection. Intracranial paradural abscesses tend to evolve rapidly, often producing irreversible damage to underlying neural structures. Antibiotics alone are inadequate, and neurosurgical drainage remains the mainstay of therapy. MRI has greatly aided in the rapid identification and management of intracranial paradural abscesses.

Cranial epidural abscesses most commonly occur adjacent to the frontal sinus, but if left untreated, infection can spread into the subdural space or even parenchyma. The abscess may be due to trauma but, most commonly, is a complication of sinusitis, which is reflected in the microbiology of cranial epidural abscesses.¹⁹⁵ Treatment requires emergent surgical drainage followed by antibiotics tailored against the bacteria cultured intraoperatively.

Cranial subdural empyema may be clinically indistinguishable from meningitis or a brain abscess, with the triad of fever, headache, and altered consciousness seen at presentation in approximately 50% of patients.¹⁹⁶ A subdural abscess is most commonly a complication of a prior neurosurgical procedure but can also occur following infection of the paranasal sinuses and, less commonly, the ears or mastoids.¹⁹⁷ Rarely, spontaneous development of a subdural abscess

following bacteremia has been reported. The microbiology of these infections reflects the pathophysiology. Infections following a neurosurgical procedure are typically due to skin flora such as *Staphylococcus* or *Enterobacteriaceae*. Infections that occur as a complication of upper respiratory tract infections are usually due to streptococci, pneumococci, *Haemophilus*, anaerobes, and staphylococci. Gram-negative enteric bacilli or *P. aeruginosa* may be associated with middle ear and mastoid infections. As with cranial epidural abscess, surgical drainage is crucial for treatment, followed by prolonged use of antibiotics.¹⁹⁵

Spinal Paradural Abscess

The incidence of spinal epidural abscess has increased in the past two decades, which is likely related to improved diagnostics with MRI and increases in comorbidities predisposing to infection. Risk factors for spinal epidural abscess include prior spinal surgery or trauma, injection drug use, diabetes, and end-stage renal dysfunction.¹⁹⁸ Patients typically present with localized spinal pain, with fever present in less than 50% of cases.^{199,200} In the absence of treatment, symptoms usually progress through four clinical phases: spinal ache, nerve root pain, radicular weakness, and paralysis. The triad of back pain, fever, and progressive neurologic deficits strongly suggests this syndrome; however, the presence of any of these signs or symptoms should raise concern for the diagnosis.

Diagnosis hinges on visualization of a collection in the epidural space (Fig. 124-4). The diagnostic study of choice is MRI, which defines cord compression and the presence and extent of abscess, identifies drainable paraspinal fluid collections, and detects concomitant vertebral osteomyelitis. Other procedures such as myelography and CT scanning may be used if MRI cannot be performed.

S. aureus accounts for more than two-thirds of cases of epidural abscess.^{199,201} Although most cases are community acquired, an increasing number are due to spinal instrumentation (surgery or nerve block), and nosocomial flora such as MRSA or *Pseudomonas* may be causative in this population. Other risk factors for spinal epidural abscess include IV drug use, diabetes mellitus, trauma, and comorbid conditions such as malignancy or alcohol use.¹⁹⁹ Empiric therapy is directed against the most likely organisms and typically includes vancomycin and an antipseudomonal agent such as cefepime. Therapy should be refined once cultures confirm a causative pathogen.

Emergency neurosurgical intervention is considered mandatory for a spinal paradural abscess if there is neurologic compromise. A recent retrospective study found that 41% of patients with a spinal epidural abscess failed medical therapy and that neurologic outcomes were improved for patients with immediate rather than delayed neurosurgical decompression.²⁰² Progressive weakness mandates the need for immediate MRI and neurosurgical consultation because decompression within 24 hours offers the best chance of neurologic recovery.²⁰¹

SEPSIS SYNDROME WITH CENTRAL NERVOUS SYSTEM INVOLVEMENT

In sepsis syndrome, an acutely ill patient develops CNS dysfunction late in the course of the illness, typically in the setting of multiorgan system failure. Altered mental status, attributable to hypotension and hypoperfusion, ranges from confusion to obtundation. Seizures may occur due to metabolic abnormalities, ischemia, or hemorrhage. In treating such patients, general supportive measures take precedence over CNS concerns. After a brief assessment, general life-support measures should correct hypotension, hypoxia, and anuria. Following blood culture, broad-spectrum antimicrobials should be administered. A careful history should be taken and physical examination performed. When findings suggest a focal infection of the CNS, directed evaluation through neuroimaging and lumbar puncture is warranted.

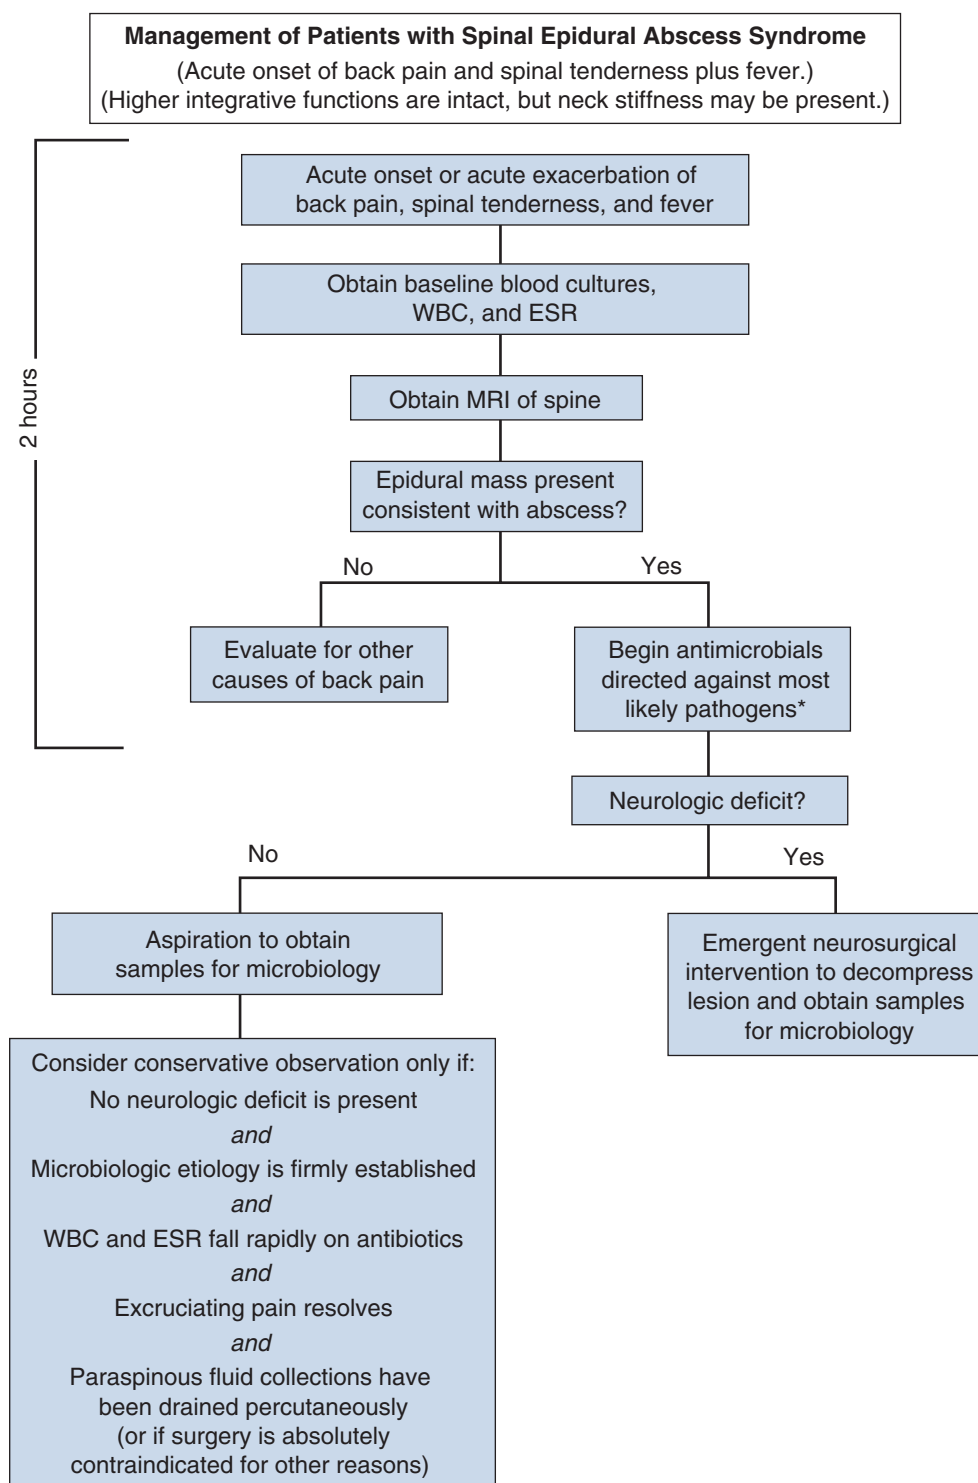

FIGURE 124-4 ■ Algorithm for the management of patients with the spinal epidural abscess syndrome. If magnetic resonance imaging (MRI) cannot be performed, myelography, high-contrast computed tomography (CT), or CT-myelography may be an acceptable alternative to localize an epidural abscess. *If abscess drainage can be performed promptly, antimicrobial drugs may be withheld until specimens for microbial analysis is obtained. ESR, erythrocyte sedimentation rate; WBC, white blood cell.

CONCLUSION

Acute infection of the CNS requires rapid therapeutic intervention. The four major syndromes of CNS infection (acute meningitis syndrome, subacute CNS infection syndrome that includes brain abscess, viral meningitis and encephalitis, spinal epidural abscess, and sepsis syndrome) differ in their signs and symptoms as well as in the approach

to definitive diagnosis and therapy. Moreover, diverse infectious and noninfectious causes may produce similar CNS syndromes. For therapy to be maximally effective, it must be instituted rapidly following the initial evaluation. Thus, in the practice of critical care medicine involving CNS disease, the goal remains the rapid institution of empiric therapy for treatable infectious syndromes while efficiently working to identify the specific disease process.

KEY POINTS

Bacterial Meningitis

1. Fever, headache, and meningismus are the classic presenting signs and symptoms of bacterial meningitis; however, absence of any one (or all) of these features may be seen.
2. A noncontrast head CT should precede lumbar puncture in the presence of papilledema, focal findings on neurologic examination, immunocompromise (human immunodeficiency virus [HIV] infection, malignancy, or transplant), and seizures in the week prior to presentation or coma.
3. Empiric antibiotic therapy should begin as soon as possible after appropriate cultures have been obtained; these can be modified later based on results of cerebrospinal fluid (CSF) Gram stain and culture.
4. Patients with negative cultures and limited clinical response after 48 hours of therapy should undergo repeat lumbar puncture and head CT or MRI scans.
5. Corticosteroid treatment in adults is controversial, but initial combination therapy with dexamethasone and antibiotics has been associated with improved outcomes in patients with pneumococcal meningitis.

Brain Abscess

1. MRI with contrast is superior to CT for imaging brain abscesses, especially in the early stages of infection.
2. Microbiology of brain abscesses is dependent on the route of infection; abscesses spreading from a contiguous focus are frequently polymicrobial.
3. Treatment of brain abscesses typically requires neurosurgical drainage and prolonged administration of antibiotics tailored to culture results.

Encephalitis

1. An infectious cause of encephalitis is found in less than 50% of cases.

2. Herpes simplex virus (HSV) must be included in the differential diagnosis of all cases of encephalitis, as this infection has a high morbidity and mortality unless treated with acyclovir. Herpes simplex encephalitis typically presents with temporal lobe lesions on MRI, and HSV polymerase chain reaction of CSF is more than 95% sensitive for diagnosis.
3. Autoimmune syndromes such as NMDAR encephalitis may mimic infectious etiologies but are treated with removal of the antigenic stimulus (i.e., surgical excision of a teratoma) and immunotherapy.

Central Nervous System Infection in HIV-Infected Patients

1. HIV-infected patients are at risk for a number of opportunistic infections. Because many of these cause mass lesions, CT or MRI should be performed before lumbar puncture.
2. Ring-enhancing lesions seen on neuroimaging are most frequently due to either toxoplasmosis or lymphoma. In patients with positive *Toxoplasma* serology, empiric therapy for 2 weeks is indicated; brain biopsy should be performed in patients with lack of radiographic improvement.
3. Cryptococcal meningitis can be rapidly diagnosed by the detection of cryptococcal antigen in either the serum or the CSF.

Epidural Abscess

1. Epidural infections typically present with back pain, fever, and progressive neurologic impairment. Diagnosis is confirmed by MRI.
2. In the presence of impaired neurologic function, surgical drainage is imperative; there is little chance of recovery if symptoms have been present for more than 24 hours before decompression. Empiric antibiotics to cover staphylococci and enteric gram-negative rods should be continued until culture results are available.

Brouwer MC, McIntyre P, Prasad K, van de Beek D. Corticosteroids for acute bacterial meningitis. *Cochrane Database Syst Rev*. 2015 Sep 12;9:CD004405. doi: 10.1002/14651858.CD004405.pub5. Review. PubMed PMID: 26362566.

This meta-analysis of 25 studies involving more than 4000 patients examined outcomes in patients with bacterial meningitis treated with corticosteroids in addition to antibiotics. There was no significant difference in mortality, hearing loss, or neurologic sequelae in patients treated with steroids. On subgroup analysis, adjuvant use of corticosteroids reduced mortality associated with S pneumoniae meningitis, and hearing loss in children with H. influenzae meningitis. When the study was stratified by site, co-administration of corticosteroids in high-income (developed) countries was associated with statistically significant reduction in hearing loss and neurologic morbidity. There was no beneficial effect of corticosteroids in patients with bacterial meningitis in low-income countries.

This paper summarized the results of a large population-based laboratory surveillance program for bacterial meningitis performed in selected areas in the United States between 1998 and 2007. During this time period, there was a 31% overall decrease in the incidence of bacterial meningitis due to declining rates of pediatric meningitis from S. pneumoniae and H. influenzae due to vaccination. The median age of patients increased from 30.3 years to 41.9 years, with an aggregate case fatality rate of 14.8%. S. pneumoniae remained the leading cause of bacterial meningitis, accounting for 58% of cases.

The authors provide expert consensus recommendations on a working case definition for encephalitis and outline diagnostic algorithms for both pediatric and adult patients with encephalitis. These protocols were developed to include the most prevalent pathogens and to optimize empiric therapy of treatment etiologies. Clinicians are encouraged to pursue additional diagnostic testing based on local epidemiology, seasonality, specific exposures, or clinical characteristics.

Graus F, Titulaer MJ, Balu R, Benseler S, Bien CG, Cellucci T, Cortese I, Dale RC, Gelfand JM, Geschwind M, Glaser CA, Honnorat J, Höftberger R, Iizuka T, Irani SR, Lancaster E, Leypoldt F, Prüss H, Rae-Grant A, Reindl M, Rosenfeld MR, Rostásy K, Saiz A, Venkatesan A, Vincent A, Wandering KP, Waters P, Dalmau J. A clinical approach to diagnosis of autoimmune encephalitis. *Lancet Neurol*. 2016 Apr;15(4):391-404. doi: 10.1016/S1474-4422(15)00401-9. Epub 2016 Feb 20. Review. PubMed PMID: 26906964.

In the past decade autoimmune disorders have been increasingly recognized as leading causes of encephalitis. These inflammatory etiologies may mimic infectious causes, but the treatment involves immunosuppressive medications rather than antimicrobial agents. This consensus statement by experts in the field of neuroimmunology provides an evidence-based strategy to guide diagnostic testing and identify a subset of patients most likely to benefit from empiric immunotherapy.

Brouwer MC, Tunkel AR, McKhann GM 2nd, van de Beek D. Brain abscess. *N Engl J Med*. 2014 Jul 31;371(5):447-56. doi: 10.1056/NEJMra1301635. Review. PubMed PMID: 25075836.

This comprehensive review provides updated information regarding the pathogenesis, epidemiology, clinical presentation, microbiology, and optimal treatment of brain abscesses. The authors emphasize the role of surgical management and highlight the increasing use of stereotactic biopsy as a less invasive means of identifying the causative organism(s) and providing therapeutic drainage.

Kim SD, Melikian R, Ju KL, Zurakowski D, Wood KB, Bono CM, Harris MB. Independent predictors of failure of nonoperative management of spinal epidural abscesses. *Spine J*. 2014 Aug 1;14(8):1673-9. doi: 10.1016/j.spinee.2013.10.011. Epub 2013 Oct 30. PubMed PMID: 24373683.

This retrospective, case-control study compared outcomes among adult patients with nonsurgical spinal epidural abscess treated medically compared to those who underwent surgical decompression in addition to antibiotic therapy. Patients with neurologic compromise, age more than 65 years, diabetes mellitus, or infection due to methicillin-resistant Staphylococcus aureus had significantly higher rates of failure with solely medical management, and consideration of early surgical intervention in these populations is warranted.

Infections of the skin, soft tissue, and muscle include a broad range of diseases commonly encountered in intensive care units (ICUs) and are often potentially life-threatening. These infections include necrotizing soft-tissue infections (NSTIs), soft-tissue infections of the head and neck, and infectious complications of bites, burns, and pressure ulcers.

NECROTIZING SOFT-TISSUE INFECTIONS

NSTIs represent a spectrum of infectious processes that are extensive and rapidly progressive. Based on the depth of skin and soft-tissue involvement, NSTIs are divided into three categories: (1) necrotizing cellulitis, (2) necrotizing fasciitis, and (3) myonecrosis. Table 125-1 shows the classification of NSTIs. The sine qua non of these infections is the necrosis of subcutaneous tissue, fascia, and muscle, with the widespread undermining of the skin. The lack of anatomic boundaries and the fact that the infection is deep within the skin help account for the severity of the infection, as well as the frequent delay in its recognition. The trunk, extremities, and perineum are the most common sites of NSTIs, but any anatomic site may be involved. For example, intraabdominal abscess, bowel perforation, and pancreatitis can all present as a necrotizing infection of the abdominal wall or extend into the thigh. Similarly, cervical fasciitis due to dental or neck abscess can extend to the mediastinum.

Pathogenesis

Pathophysiologic factors involved in the development and progression of NSTIs are host resistance, the bacterial pathogens involved, and local barrier factors. Early development of systemic organ dysfunction and a lack of early resolution is associated with higher morbidity and mortality rates.¹

Host Resistance

As shown in Table 125-2, individuals who are immunocompromised or have chronic diseases are more likely to develop necrotizing skin and soft-tissue infections than those without such medical problems.

Bacterial Pathogens

Although necrotizing cellulitis and fasciitis may be caused by a single bacterial pathogen (e.g., group A *Streptococcus*, *Vibrio* spp., or zygomycetes), about 80% of necrotizing cellulitis or fasciitis results from polymicrobial infections with synergistic facultative aerobes and anaerobic gas-forming organisms. An average of 4.4 organisms are isolated from polymicrobial necrotizing infections.² The former include gram-positive and gram-negative aerobes, such as *Streptococcus pyogenes*, *Staphylococcus aureus*, *Enterococcus faecalis*, *Escherichia coli*, or *Pseudomonas aeruginosa*, and the latter include *Clostridium perfringens*, *Bacteroides fragilis*, and *Peptostreptococcus*.³ Certain predisposing conditions can be correlated with specific bacteria; for example, trauma with *Clostridium* spp., diabetes mellitus with *Bacteroides* spp., *S. aureus*, and Enterobacteriaceae, as well as immunosuppression with *Pseudomonas* spp. and Enterobacteriaceae. Rare monomicrobial infections by *Haemophilus influenzae* have been described recently.

Traditionally, gas gangrene is synonymous with clostridial infection, and gas in the soft tissue is thought to be a grave finding. The majority of gas-producing infections do not involve *Clostridium* spp. but are instead necrotizing infections due to other bacterial pathogens. Many bacteria, especially facultative gram-negative bacilli (e.g., *E. coli*), produce insoluble gasses (e.g., hydrogen, nitrogen, and methane) whenever they are forced to use anaerobic metabolism. Thus, the presence of crepitus in a soft-tissue infection found during physical examination or radiographs imply anaerobic metabolism and the existence of an NSTI.

Local Barrier Failure

Most serious soft-tissue infections require some degree of tissue injury and a break in the skin to establish infection. The break in the skin may be due to a surgical incision or trauma, but in a significant percentage of cases, it is difficult to find evidence of a break in the skin or soft-tissue trauma.

Clinical Manifestations and Diagnosis

The critical aspect of diagnosing NSTIs is maintaining a high index of suspicion, which allows for early recognition of the necrotizing nature of the infection and the need for surgical intervention. Although necrotizing cellulitis and fasciitis may occur after an injury, up to 40% of NSTIs have no identifiable cause. NSTIs with identifiable barrier failure are more likely to be polymicrobial and are easier to diagnose than the more virulent infections caused by a single organism. In necrotizing cellulitis, gas is invariably found in the skin, but the fascia and deep muscle are spared. Early clinical findings are similar to those of common wound infections, including local edema (89%), erythema (30%), fever (71%), and local cutaneous anesthesia (27%) due to cutaneous nerve necrosis. These are followed by gangrenous skin changes with rapid extension beyond the borders of the original infection. Synergistic polymicrobial necrotizing fasciitis is characterized by "dishwater pus." Patients usually have a high fever, but no obvious source of clinical infection can be detected. Pain in the area of the infection is usually out of proportion with the physical findings. Diagnosis may be more difficult in patients with immunosuppression, resulting in delays in treatment and higher mortality rates.⁴ As the infection progresses, patients develop shock and multiple organ failure. Mortality rates are high, with necrotizing fasciitis being fatal in 23.5% of cases.⁵

Clostridial myonecrosis typically develops within 12 to 24 hours after a traumatic event or the closure of a deep, contaminated wound. Recurrent gas gangrene caused by *C. perfringens* has been described in individuals with nonpenetrating injuries at the sites of previous clostridial myonecrosis, where spores of *C. perfringens* remain quiescent in the tissue and then germinate when minor trauma provides conditions suitable for growth. Patients present with the triad of severe pain, tachycardia out of proportion to fever, and crepitus in the soft tissue. Once overt gangrene with edema and bronze, purplish, or brown discoloration with bullae and watery discharge occur, the disease is at an advanced stage. Gram staining of the exudate shows gram-positive rods occasionally accompanied by other flora. In contrast, streptococcal myonecrosis usually develops over 2 to 4 days after the trauma or closure of a wound. The onset is not as rapid, patients do not appear

TABLE 125-1 Classification of Necrotizing Skin, Soft-Tissue, and Muscle Infections

| DISEASE | BACTERIOLOGY | COMMENTS |
|--|--|--|
| NECROTIZING CELLULITIS | | |
| Clostridial cellulitis | <i>Clostridium perfringens</i> | Local trauma, recent surgery; facial/deep muscle spared |
| Nonclostridial cellulitis | Mixed: <i>Escherichia coli</i> , <i>Enterobacter</i> , <i>Peptostreptococcus</i> spp., <i>Bacteroides fragilis</i> | Diabetes mellitus predisposes; produces foul odor |
| Meleney's synergistic gangrene | <i>Staphylococcus aureus</i> , microaerophilic streptococci | Rare infection; postoperative; slowly expanding, indolent, ulceration in superficial fascia |
| Synergistic necrotizing cellulitis | Mixed aerobic and anaerobic, including <i>B. fragilis</i> , <i>Peptostreptococcus</i> spp. | Diabetes mellitus predisposes; variant of necrotizing fasciitis type I; involves skin, muscle, fat, and fascia |
| NECROTIZING FASCIITIS | | |
| Type I | Mixed aerobic and anaerobic; staphylococci, <i>B. fragilis</i> , <i>E. coli</i> , group A streptococci, <i>Peptostreptococcus</i> spp., <i>Prevotella</i> , <i>Porphyromonas</i> spp., <i>Clostridium</i> spp. | Usually requires a breach in the mucous membrane layer either through surgery, penetrating injuries, or from chronic medical conditions such as diabetes, peripheral vascular disease, malignancy, and anal fissures |
| Type II | Group A streptococci | Increasing in frequency and severity since 1985; very high mortality; often begins at the site of nonpenetrating minor trauma such as a bruise or muscle strain but there is often no identified precursor Predisposing factors: blunt/penetrating trauma, varicella (chickenpox), intravenous drug abuse, surgical procedures, childbirth, NSAID use |
| MYONECROSIS | | |
| Clostridial myonecrosis | <i>Clostridium</i> spp. | Predisposing factors: deep/penetrating injury, bowel and biliary tract surgery, improperly performed abortion and retained placenta, prolonged rupture of the membranes, and intrauterine fetal demise or missed abortion in postpartum patients. Recurrent gas gangrene occurs at sites of previous gas gangrene. |
| Streptococcal myonecrosis | Streptococci | |
| SPECIAL TYPE OF NECROTIZING SOFT-TISSUE INFECTION | | |
| Fournier's gangrene | Polymicrobial, with <i>E. coli</i> the predominant aerobe and <i>Bacteroides</i> the predominant anaerobe. Other microflora: <i>Proteus</i> , <i>Staphylococcus</i> , <i>Enterococcus</i> , aerobic and anaerobic <i>Streptococcus</i> , <i>Pseudomonas</i> , <i>Klebsiella</i> , and <i>Clostridium</i> | Necrosis of the scrotum or perineum that starts with scrotal pain and erythema and rapidly spreads onto the anterior abdominal wall and gluteal muscle. It is more often seen in diabetics and can be associated with trauma. |

TABLE 125-2 Factors Predisposing to Necrotizing Soft-Tissue Infections

Human, animal, or insect bites
 Contaminated or dirty surgical procedures
 Diabetes mellitus
 Long-term corticosteroid use
 Malignancy
 Trauma/burns
 Intravenous drug abuse
 Chronic alcoholism
 Malnutrition
 HIV infection/AIDS
 Cirrhosis
 Peripheral vascular diseases
 Chronic renal failure

as sick, pain is not as severe, and gas formation is not as obvious as in those with clostridial myonecrosis.

Management

The initial management of NSTIs involves aggressive fluid resuscitation, appropriate broad-spectrum parenteral antibiotics, and most important, expedient and radical surgical débridement. Other adjunctive therapies (e.g., hyperbaric oxygen, immunoglobulin, and immune-modulating peptide drugs) have been used, but the evidence for their efficacy at this time is not definitive.

Antibiotics

For type I necrotizing fasciitis (mixed aerobic and anaerobic), antibiotic treatment should be guided initially by the results of the Gram stain. Early empiric treatment should be initiated with extended-spectrum penicillins (e.g., ampicillin-sulbactam, piperacillin-tazobactam, and ticarcillin-clavulanic acid) or carbapenem antibiotics (e.g., imipenem-cilastatin) plus a drug that targets methicillin-resistant *S. aureus* (MRSA). If there is a suspicion that resistant coliforms might be participating (e.g., in patients who have been hospitalized or who have been treated with antibiotics recently or where there is suspicion of rectal or intestinal involvement), a third-generation cephalosporin, aminoglycoside, or aztreonam combined with either clindamycin or metronidazole may be used. For those patients with severe cases or in whom clostridia are suspected, clindamycin in addition to penicillin is useful for inhibiting toxin production. The incidence of community-acquired MRSA (CA-MRSA) in necrotizing soft tissue infections is increasing and mandates appropriate coverage.⁵ Linezolid is emerging as the preferred treatment; a meta-analysis demonstrated improved clinical and microbiological cure rates when compared to vancomycin.⁷

Although there are no data from clinical trials establishing the benefit of combined therapy in type II necrotizing fasciitis (group A streptococci), penicillin G combined with clindamycin is the antibiotic therapy of choice. Clindamycin is recommended not for its anti-anaerobic properties but because of its additional activity against gram-positive organisms, including the specific inhibition of toxin production.⁸ Cefotaxime and ceftriaxone are acceptable alternatives. For patients allergic to penicillin, vancomycin is the recommended treatment.

FIGURE 125-1 ■ Necrotizing fasciitis of the abdominal wall after extensive débridement and the application of a porcine dermal collagen implant for temporary abdominal closure (*left*) and after healing of the anterolateral thigh flaps to reconstruct the abdominal wall (*right*).

Surgical Intervention

Early surgical débridement is critical in the management of NSTIs.⁹ Aggressive surgical excision of all involved tissue with a margin of normal-appearing tissue is mandatory. All necrotic tissue should be excised back to healthy bleeding margins. The wound should frequently be reexamined for the viability of the tissue, and repeat operative débridement is frequently required. Aggressive fascial débridement of abdominal surgical wounds may necessitate the use of prosthetic material to replace an abdominal wall defect, as depicted in Figure 125-1. In Fournier's gangrene and perineal/perirectal NSTI, a colostomy or fecal management system may be necessary to keep the wound clean. The testes generally survive because their blood supply is usually spared, but they may need to be temporarily implanted in the soft tissue of the medial thighs if the scrotum must be débrided. On a rare occasion, NSTI of the extremities may require amputation.

Myonecrosis or gas gangrene requires radical débridement to viable muscle. When this process involves the extremities, control of the infection is more easily achieved, although as mentioned previously, amputation may be necessary. In contrast, clostridial myonecrosis involving the trunk may present some very difficult therapeutic decisions because the removal of nonviable tissue may leave the peritoneal or thoracic cavities open.

Adjunctive Therapy

Hyperbaric Oxygen. The use of hyperbaric oxygen (HBO) in NSTIs is controversial. Although there are no prospective randomized studies of HBO in these infections, *in vitro* data and reviews of clinical series show beneficial effects of HBO when combined with antibiotics and surgical débridement in the management of clostridial infection.¹⁰ A retrospective analysis of the University Health Consortium (UHC) database showed that complications and mortality were reduced in patients with a high severity of illness scores.¹¹ Hyperbaric oxygen is toxic to clostridia and inhibits bacterial growth, blocks the production of alpha-toxin, and preserves marginally perfused tissue. Debate also exists regarding the use of HBO for nonclostridial necrotizing skin and soft-tissue infection, with one report suggesting reduced mortality.¹⁰ Despite these results, HBO therapy is not widely utilized; only 7% of NSTI patients in academic medical centers with HBO capabilities actually received HBO.¹¹

Intravenous Immunoglobulin. Intravenous immunoglobulin (IVIG) has been administered to patients with streptococcal and staphylococcal toxic shock syndrome and may be efficacious in the treatment of

this toxin-mediated disorder. Some studies have demonstrated that IVIG has some beneficial effect for the treatment of NSTIs, theoretically owing to its neutralization of circulating clostridial toxins and streptococcal superantigens.¹² However, a large multicenter retrospective cohort study of children with streptococcal toxic shock syndrome showed no improvement in outcomes with the administration of IVIG.¹³ A recent Swedish prospective study did demonstrate improvement with the use of IVIG.¹⁴ There is no clear consensus at this time regarding the efficacy of IVIG.

CD28-Mimetic Peptide. An immune-modulating short peptide has been shown in phase II trials to reduce the rates of organ failure, ventilator days, ICU days, and the number of débridements required for severe NSTI.¹⁵ This agent acts by binding the CD28 receptor, blocking the activation of T-cell receptors and attenuating the response to streptococcal exotoxin A.¹⁶

IMPORTANT SOFT-TISSUE INFECTIONS OF THE HEAD AND NECK

Ludwig's Angina

Ludwig's angina is a potentially life-threatening, rapidly progressive, diffuse "woody" or brawny cellulitis of the submandibular and sublingual spaces that occurs most often in young adults with dental infections.

Pathogenesis

In adults, 50% to 80% of cases of Ludwig's angina are caused by dental caries, and the disease has a mortality rate of 5% to 10%. Submandibular and sublingual spaces freely communicate, and with the involvement of the deep cervical fascia, the infection may spread rapidly. Extension of the carotid sheath or the retropharyngeal space can cause mediastinitis; in a series of 130 patients, 28% had mediastinitis.¹⁷ Infection is commonly caused by oral cavity anaerobes such as *Fusobacterium*, anaerobic streptococci, *Bacteroides*, spirochetes, and hemolytic *Streptococcus* organisms, although the infection may be mixed with *Staphylococcus* and *Streptococcus*, *Klebsiella*, or a combination of aerobic or anaerobic organisms.¹⁸

Clinical Manifestations

The patient is febrile and complains of severe neck pain and swelling, odynophagia, dysphagia, drooling, and leaning forward to maximize

the airway diameter. Patients usually have a recent history of dental work, obviously poor dental hygiene, or deep neck abscess.

The examination may reveal a tender, symmetric, and indurated swelling, sometimes with palpable crepitus in the submandibular area. The tongue may be swollen or displaced upward and backward, and the mouth is held open because of the lingual swelling. The presence of stridor, dyspnea, or decreased air movement suggests airway compromise. The appearance of significant asymmetry of the submandibular area is an ominous sign because it may represent an extension of the inflammation to the parapharyngeal space.

Radiographic imaging may indicate the source of the infection, soft-tissue swelling around the airway, and possibly submandibular gas.

Management

Control of the Airway. Progression from the first findings of symptoms to asphyxia may occur rapidly over several minutes to a few hours. Therefore, airway protection is a critical component of initial management. In the past, the standard of care for Ludwig's angina was early emergency intubation or tracheostomy to protect the airway. However, this practice has gradually been abandoned. Recent data show that most cases can be managed initially by close observation in a critical care unit and intravenous antibiotics.¹⁹ If an artificial airway is required, flexible fiberoptic-guided nasotracheal intubation is the preferred method of airway control. Tracheostomy, under local anesthesia and performed through the cellulitis, remains the most widely recommended means of obtaining a surgical airway.

Antibiotics and Other Pharmacotherapy. Penicillin and clindamycin are the antibiotics of choice for treating Ludwig's angina. Ampicillin-sulbactam, metronidazole and penicillin, imipenem-cilastatin, piperacillin-tazobactam, as well as second and third-generation cephalosporins are other reasonable choices for treating obligate anaerobes that are most commonly encountered in this infection. Coverage for MRSA may be required based on patient and local factors.

Corticosteroids have been used empirically to treat airway edema. The value of corticosteroids in the setting of Ludwig's angina is unclear, and they are likely not indicated.²⁰

Surgical Intervention. Surgical débridement may only moderately improve the airway. Surgical incision and drainage were the therapies of choice in the preantibiotic era. Unless antibiotic therapy is significantly delayed, it is unlikely that pus will be identified, because purulent collections develop relatively late. With the exception of dental extraction, surgery is reserved for those patients who do not respond to medical therapy and those with crepitus and purulent collections.²¹ Any patient requiring surgical intervention should have an artificial airway in place before neck exploration. The location of abscesses should be identified using CT or magnetic resonance imaging (MRI). Infection localized above the carina is usually addressed by cervical incision, but infection below the carina requires the additional surgical drainage of the mediastinum.²²

Acute Epiglottitis

Acute epiglottitis is a rare, potentially life-threatening bacterial infection causing inflammation and edema of the epiglottis, aryepiglottic folds, and surrounding tissues. Before the era of *Haemophilus influenzae* vaccination, epiglottitis used to be a primarily pediatric infection. However, in recent years, the infection has become primarily an adult disease.

Pathogenesis

Invading bacteria cause inflammation and edema of the epiglottis, aryepiglottic fold, and the surrounding tissues. These structures may then protrude downward and over the glottic opening, causing an airway obstruction. In the past, most of the cases (50%-70%) were caused by *H. influenzae* B (HIB).²³ However, at present, other bacteria, including group A β -hemolytic *Streptococcus*, *S. aureus*, and *Streptococcus pneumoniae*, have become more common, and more patients present with an epiglottic abscess.

Clinical Manifestations and Management

Early signs of epiglottitis include hoarseness, dysphagia, odynophagia, and a sore throat (present in 94% of patients).²⁴ Some authors advocate direct or indirect laryngoscopy on adult patients without respiratory distress. The most common misdiagnosis is streptococcal pharyngitis. Patients who can maintain their airway and adequate oxygenation should be closely observed in an ICU. Corticosteroids, racemic epinephrine, and heliox can be considered for initial management, but their role is unresolved. Dyspnea and stridor indicate impending airway obstruction, and emergency airway control should be established. Flexible fiberoptic laryngoscopy is usually used during intubation.

The third-generation cephalosporins, cefotaxime, and ceftriaxone are the antibiotics of choice for acute epiglottitis. These antibiotics are usually effective against *H. influenzae*, streptococci, and staphylococci. A number of other antibiotics including cefuroxime, ampicillin-sulbactam, piperacillin-tazobactam, ticarcillin-clavulanic acid, and levofloxacin are also effective in epiglottitis.

INFECTIONS OF BITE WOUNDS

Exposure to mouth flora occurs in bite wounds, clenched-fist injuries, and finger or thumb sucking. The incidence of infection after cat bites can be more than 50%, and infection after dog or human bite wounds can be 15% to 20%. Although the majority of patients with bite wounds do not seek medical attention, some bite wounds can lead to severe infections (i.e., NSTIs) and sepsis that results in loss of limb function or even requires amputation. Complications also include lymphangitis, septic arthritis, tenosynovitis, and osteomyelitis.

Pathogenesis

The microbiology of bite wounds is generally polymicrobial, reflecting the aerobic and anaerobic microbiology of the biter's oral flora and the skin of the victim.²⁵ Aerobes (*Eikenella corrodens*, *Staphylococcus*, *Streptococcus*, and *Corynebacterium* spp.) are the most common isolates from infected human bite wounds. *E. corrodens* is a slow-growing, gram-negative bacillus frequently associated with chronic infection and abscess formation in human bites. Commonly isolated anaerobes in human bites include *Bacteroides* and *Peptostreptococcus* spp., and *Pasteurella multocida* is the most prevalent organism found in 50% of dog bite wounds and 70% of cat bite wound infections.^{26,27} *S. aureus*, α -, β -, and δ -hemolytic streptococci, gram-negative organisms, and anaerobic microorganisms are frequently isolated from infected animal bites.

Management

Management goals for bite wounds are to prevent or appropriately treat infection and minimize soft-tissue deformities. For domestic animal bites, unless the animal is suspected of having rabies, rabies prophylaxis is not necessary. Many wild animals including, skunks, raccoons, foxes, and bats should be considered rabid unless proved otherwise, and a bite by such an animal should result in rabies prophylaxis. The tetanus immunization status must also be determined and the appropriate treatment administered.

Meticulous wound care is the cornerstone of human or animal bite wound management. Copious irrigation and careful débridement of the wound decrease the incidence of wound infection. Facial wounds may be closed primarily after débridement and irrigation without an increased risk of infection.²⁸ Immediate closure of bite wounds of the hand remains a controversial issue, but irrigation followed by delayed primary closure may be appropriate.²⁹

Cultures of clinically uninfected wounds are not indicated but should be performed in infected wounds that are not improving despite apparently adequate antibiotic treatment. In bite victims, prophylactic broad-spectrum antibiotics are recommended for patients

with high-risk bites but are only of proven benefit in human bites.³⁰ The risk factors for infection include human bites, wounds of the hand, foot, face, scalp, and perineum, puncture wounds, crush wounds, bites over vital structures (e.g., artery, nerve, or joint), a patient age older than 50 years, or immunosuppression. In most patients, amoxicillin-clavulanic acid is the preferred antibiotic. Alternatives include moxifloxacin, amoxicillin, doxycycline, and cefuroxime. In human bites, the amoxicillin-clavulanic acid will cover *E. corrodens* and most other oral flora. Other options include second- or third-generation cephalosporins, quinolones, or doxycycline. In patients who are allergic to penicillin, trimethoprim-sulfamethoxazole is an alternative for both dog and cat bites, whereas quinolones or erythromycin may be used for human bites.

Patients with complex wounds, sepsis, established infection, suspicion of musculoskeletal, neurologic, or vascular involvement, diabetes, or immunosuppression should be treated with parenteral antibiotics, irrigation, and débridement with cultures.³¹ Consultation with a hand surgeon should be considered for hand wounds, because of the higher risk of severe infection compared to other sites.

INFECTIOUS OF BURN WOUNDS

Burn wound infection/sepsis is one of the most common causes of death in burn patients. The highest risk of bacterial invasion from the skin flora into the eschar occurs 5 to 7 days after the burn. Mechanisms of burn wound infection include the breakdown of the natural cutaneous barrier, compromised host defenses, and exposure to pathogenic and opportunistic bacteria. The surface of a burn contains a large amount of necrotic tissue and protein-rich wound exudate, so it provides an excellent growth medium for surface bacteria, leading to bacterial colonization and invasion. Burns are also associated with an immunocompromised status. The percentage of total body surface area (TBSA) that is burned and the duration of hospitalization correlate well with the incidence of wound infections.³² The predisposing factors for the development of burn wound infection are listed in Table 125-3.

Pathogenesis

After a thermal injury, all burn wounds become contaminated with microorganisms, either from the patient's endogenous flora or resident microorganisms in the burn unit. This colonization occurs initially without clinical significance. However, surface-colonizing bacteria can penetrate the avascular eschar and proliferate beneath the eschar at the viable/nonviable tissue interface. When host defense mechanisms are compromised, bacteria can break this barrier and spread systemically, resulting in bacteremia and sepsis.

The most common organisms found in burn wound infections are bacteria, and 70% to 90% are endogenous to the patient. Bacterial organisms can also be acquired by cross-infection, principally from the hands of healthcare professionals. Before the era of penicillin, streptococci and staphylococci were the predominant pathogens. Since the 1950s, *P. aeruginosa* has become the most important species.³³

Other important bacterial species include *S. aureus*, group A *Streptococcus*, *Enterobacter cloacae*, *E. faecalis*, *Klebsiella* spp., and *Acinetobacter* spp.³⁴ Fungi, especially *Candida albicans* and *Aspergillus* spp., and viruses (herpesvirus) are also commonly isolated from infected burn wounds.³⁵

Clinical Manifestations and Diagnosis

Successful treatment of burn wound infections largely depends on the early detection of infection. Burn wound infection is difficult to diagnose on the basis of clinical signs and symptoms because burn-induced inflammatory responses (e.g., fever, leukocytosis) are indistinguishable from those of an infection. The local signs of infection may be absent, minimal, or late. Diagnosis is generally based on a combination of clinical signs that indicate sepsis (e.g., fever, leukocytosis, organ dysfunction, and hyperdynamic state) and the results of surveillance cultures. Any of the findings listed in Table 125-4 should raise suspicion of a burn wound infection.³⁶ The practice of culturing the burn wound surface does not accurately predict progressive bacterial colonization or incipient burn wound sepsis. Qualitative and quantitative correlations are poor between the flora on the surface of the burn wound, bacterial colonization, and the invasion of the deep layers of the eschar. It has been reported that a biopsy of the wound with quantitative cultures of greater than 10^5 CFU per gram of tissue is an accurate indicator of invasive burn wound infection.³⁷ When bacterial invasion to viable tissues is detected, excision of the infected wound is important, and systemic antibiotics are indicated.

Management

Prevention of Burn Wound Infections

Systemic antibiotic prophylaxis is not routinely administered to burn patients admitted to the hospital because the unexcised burn wound does not lead to significant bacteremia.³⁸ Frequent dressing changes with an evaluation of the burn wound and surrounding tissue allow for the early detection and therapy of cellulitis. Early excision and grafting of burn wounds have become the standard of care. *Early excision* is defined as the staged excision of all deep partial- and full-thickness burns by the third to seventh postburn day. The philosophy of early burn wound excision has resulted in improved survival in patients with TBSA burns greater than 30% to 40%, a shorter hospital length of stay, lower costs of hospital care, and fewer painful dressing changes. If for some reason (e.g., hemodynamic instability or severe respiratory failure) the patient cannot undergo grafting, temporary coverage with a porcine or cadaveric graft is performed. In lieu of this approach, surveillance wound cultures should be performed several times per week to diagnose a burn wound infection early. In addition, strict antiseptic measures such as hand washing, barrier isolation, and equipment and room cleaning decrease the incidence of wound infection.

Topical antimicrobials are commonly used in burn patients to prolong the sterility of the full-thickness burn wound, decreasing the conversion of partial-thickness to full-thickness wounds by local infection, and thereby reducing mortality. Aggressive removal of the necrotic tissue and closure of the wound with autografts is mandated. The commonly used topical agents are listed in Table 125-5.

TABLE 125-3

Predisposing Factors for Burn Wound Infections

- Burn wound greater than 30% total body surface area
- Full-thickness burn
- Extremes in patient age
- Preexisting diseases: immunosuppression, diabetes mellitus, vascular insufficiency
- Virulence and antibiotic resistance of colonizing pathogens
- Failure of skin graft
- Prolonged open burn wound
- Improper initial burn wound care

TABLE 125-4

Clinical Signs Suggestive of Burn Wound Infection

- Progression of second-degree to third-degree burn injury
- Increased pain, erythema, color changes
- Unexpected change in the appearance or depth of the wound
- Unexpected rapid eschar separation
- Metastatic septic lesion in the unburned tissue
- Systemic signs of sepsis

TABLE 125-5 Commonly Used Topical Agents in Burn Wounds

| AGENT | ADVANTAGE | DOSE | PRECAUTION |
|---|--|---|---|
| Silver sulfadiazine (SSD) | Useful for the prevention of infections from second- or third-degree burns. Bactericidal activity against many gram-positive and gram-negative bacteria; also effective against yeast. | Apply to open wounds twice or three times daily. | Does not penetrate eschar. Neutropenia. Caution in glucose-6-phosphate dehydrogenase deficiency. May increase the risk of burn wound infection. ⁴⁹ |
| Mafenide acetate cream and solution | Topical. Diffuses into the eschar and is highly effective against gram-negative organisms, including <i>Pseudomonas</i> spp. | Apply cream to open wounds twice or three times daily. Soaks with solution must be kept moist. | Pain/burning may occur. Metabolic acidosis due to inhibition of carbonic anhydrase (especially with cream). |
| Silver nitrate (0.5%) | Silver ion has broad-spectrum antibacterial activity but does not penetrate burn wound eschar; therefore, it is most effective when applied early. | Apply topically to the wound to a thickness of approximately 1.5 mm daily or twice daily as moistened dressings. | Not for internal use. Stains wound and everything else. Does not penetrate eschar. Hyponatremia. |
| Silver-impregnated silicone, gel, or mesh dressings (numerous brands) | Dressings impregnated with silver ions with broadest spectrum activity covering gram-negative organisms including <i>Pseudomonas</i> , gram-positive bacilli, methicillin-resistant <i>Staphylococcus aureus</i> , and vancomycin-resistant enterococcus. Good eschar penetration. | Apply to affected area, and monitor for adherence. If silver dressing is adherent, leave in place for 7-10 days. Some dressings should be kept moist. | Limited toxicity issues. Adherence is poor in wounds with significant exudates. |
| Mupirocin | Active against a wide variety of gram-positive bacteria, including MRSA. Also active against certain gram-negative bacteria. Exerts activity by binding to bacterial isoleucyl transfer RNA-synthetase. Good for the face. | Apply to affected areas three times a day and cover with a gauze dressing. | Prolonged use may result in the growth of resistant organisms; do not use on very large wounds where polyethylene glycol absorption is possible (especially in patients with moderate renal failure). |

Silver-impregnated silicone, gel, or mesh dressings are the preferred dressings for partial-thickness wounds.

Treatment of Burn Wound Infections

Antibiotics

Systemic antibiotics are not used prophylactically in patients with burn wounds but are reserved for use in cases of known or suspected invasive infection.³⁹ As long as bacterial culture results are available, antibiotics with the narrowest spectrum of activity should be used to minimize the development of resistant organisms. Recommendations for empiric therapy are based on the length of time since the burn was sustained, previous administration of antibiotics to the patient, and knowledge of likely pathogens and the local antibiogram. Inappropriate use of multiple antibiotics promotes the overgrowth of resistant pathogens including *Candida* spp., enterococci and does not decrease mortality.

Surgical Intervention

Invasive bacterial or fungal burn wound infections are treated with surgical excision to the level of viable tissue. Early burn wound excision significantly reduces bacterial colonization and reduces the risk of invasive burn wound infection. Patients who undergo topical treatment and delayed burn wound excision exhibit greater bacterial colonization and increased rates of infection.⁴⁰ Wounds that can be excised completely should be covered with an allograft or autograft. If complete débridement is not possible, topical antimicrobials should be applied, and the wound reexamined for possible repeat débridement.

INFECTIONS OF PRESSURE ULCERS

Pressure ulcers are caused by localized tissue necrosis and infection due to prolonged compression between a bony prominence and an external surface. Although infection of decubitus ulcers is high in the nursing home setting and spinal cord injury patients, it is an

uncommon cause of infection or sepsis in ICU patients.⁴¹ Pressure ulcers may pose a risk to other hospitalized patients by serving as a reservoir for drug-resistant organisms.

Pathogenesis and Classification

Risk factors for pressure ulcers in patients include limited physical activity, impaired sensory perception, poor nutritional status, chronic disorders (e.g., diabetes mellitus, cardiovascular disease, and cerebrovascular accidents), impaired circulation, low serum hemoglobin, and increased blood urea nitrogen and serum creatinine concentrations.⁴² Concomitant infections including cellulitis of surrounding tissue, contiguous osteomyelitis, and bacteremia are associated with infection of decubitus ulcers.⁴³

Infections of pressure ulcers are usually polymicrobial. Aerobes commonly recovered include staphylococci (including MRSA), enterococci, *Proteus mirabilis*, *E. coli*, and *Pseudomonas* spp. Anaerobic *Peptostreptococcus*, *Bacteroides fragilis*, and *Clostridium* spp. are also found in these infections. Pressure ulcers are a major reservoir of MRSA. Making an accurate microbiological diagnosis is usually impractical and difficult because all pressure ulcers are colonized with microorganisms, and a superficial culture will not distinguish between colonizing and infecting organisms. If it is necessary to determine the microbiology accurately, it is more appropriate to perform a deep-tissue biopsy or direct a needle through the intact skin and aspirate a specimen for bacterial culture from the margin of the ulcer.

Management

There are many different approaches for the treatment of pressure ulcers; however, none has demonstrated superiority.⁴⁴ Prevention of decubitus ulcers, including pressure relief with support surfaces and repositioning, appropriate nutrition, and skin moisturizers, is the best treatment.⁴⁵ Once the ulcer has been established, and an infection is present, débridement of necrotic and marginally viable tissue is

necessary to obtain healing. Topical agents such as povidone-iodine, hydrogen peroxide, and others have been widely used without significant impact. Proper use of occlusive dressings (e.g., balsam, Peru, trypsin, or castor oil preparations) increases patient comfort, enhances healing, decreases the possibility of infection, saves time, and reduces costs.⁴⁶ Topical antimicrobial agents have not been shown to be effective. Systemic antibiotic therapy should be reserved for infected ulcers. Skin grafting of clean wounds is effective if the underlying cause of the pressure ulcer has been removed. However, adequate treatment frequently requires more complex therapies, including tissue flaps and sometimes even amputation to facilitate wound closure.⁴⁷ Treatment of recalcitrant wounds can be difficult and costly. Several newer therapeutic strategies include vacuum-assisted closure, topical alginates, growth factor therapies (e.g., platelet-derived growth factor), and a variety of skin substitutes.⁴⁸

Broad-spectrum empiric antibiotic regimens are appropriate for patients with pressure ulcer-associated cellulitis, osteomyelitis, or bacteremia. Although malnutrition with protein deficiency is the most common cause of failure of these lesions to heal, osteomyelitis has to be ruled out by physical examination and imaging. If osteomyelitis is present, a more extended course of therapy is required.

KEY POINTS

1. Most serious soft-tissue infections require some degree of tissue injury and a break in the skin to establish an infection. The break in the skin may be due to a surgical incision or trauma.
2. Initial management of necrotizing soft-tissue infections (NSTIs) involves resuscitation, appropriate broad-spectrum parenteral antibiotics, as well as expedient and radical surgical débridement. Adjunctive therapies (e.g., hyperbaric oxygen and immunoglobulin) may be used, but their efficacy is not well established.
3. Topical antimicrobial agents are commonly used in burn patients, reducing local infection and mortality caused by burn wound infection. Systemic antibiotics are not used prophylactically in burn patients.

ANNOTATED REFERENCES

- Brook I. Management of human and animal bite wound infection: an overview. *Curr Infect Dis Rep* 2009;11:389–395.
This article reviewed 60 publications on bite wound infections and described the microbiology, diagnosis, and management of human and animal bite wound infections. The author pointed out that hand wounds present a special problem because 30% or more become infected.
- Cumming J, Purdue GE, Hunt JL, et al. Objective estimates of the incidence and consequences of multiple organ dysfunction and sepsis after burn trauma. *J Trauma* 2001;50:510–515.
In this prospective study, a total of 85 patients with ≥20% total body surface area burns admitted to a single center were prospectively enrolled over 1 year. The study revealed that severe multiple organ dysfunction and severe sepsis/septic shock are both related to burn size, age, and male sex, the length of ICU stay, and the duration of ventilatory support.
- Elliot D, Kufera JA, Myers RA. The microbiology of necrotizing soft tissue infections. *Am J Surg* 2000;179:361–366.
This retrospective study reviewed 182 patients with NSTIs. The authors reported that NSTIs are frequently polymicrobial, and the most common organisms are, in order, Bacteroides spp., Escherichia coli, and other gram-negative rods.

Infections of the head and neck range in severity from minor to life threatening. The intensivist is called upon to manage such patients either when they are critically ill or when airway compromise has occurred or is imminent. Besides airway management and control of sepsis, the intensivist must also be aware of the local anatomy and relevant microbiology. This knowledge will help guide the choice of antimicrobial agents as well as allow the clinician to anticipate the potential for spread of infection to related anatomic spaces and subsequent complications.

NORMAL HEAD AND NECK FLORA

Huge numbers of bacteria reside in the oral cavity in health, with the bacterial load exceeding 10^{11} /mL in the gingival crevices of patients with teeth.¹ The main bacterial species are anaerobes including *Bacteroides*, *Fusobacterium*, *Prevotella*, and *Peptostreptococcus*. Other common oral inhabitants include *Streptococcus mutans*, *Staphylococcus aureus*, *Actinomyces* spp., and *Eikenella corrodens*. Pharyngeal colonization and subsequent infection with organisms such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Streptococcus pyogenes* may also occur.

In acute illness, an additional modifying factor is the decreased production of oral mucosal fibronectin. This is of relevance to the clinician because fibronectin in normal physiologic amounts will preferentially bind gram-positive bacteria (such as *S. mutans*); however, when the production of fibronectin is decreased, there is rapid colonization of the oral cavity with gram-negative organisms, including species such as *Pseudomonas aeruginosa*.² These gram-negative organisms may then participate in head and neck infections of oral or odontogenic origin, necessitating broad nosocomial-type gram-negative antibiotic coverage when the patient has been recently hospitalized or acquired the infection in the intensive care unit (ICU).

SITES OF DEEP HEAD AND NECK INFECTION

Serious infection of the head and neck can involve the following general anatomic areas:

- Sinus
- Pharynx
- Epiglottitis
- Retropharyngeal space
- Submandibular space (Ludwig's angina)
- Lateral pharyngeal space (anterior and posterior)
- Internal jugular vein (Lemierre syndrome)

Some of these anatomic areas are connected via actual or potential spaces. Thus infection beginning in one space may spread rapidly to involve others, with potential resultant damage or destruction of vital structures. Such connections are discussed in the following sections, and differentiating features are highlighted in Table 126-1.

Predisposing factors for the development of deep neck infection include uncontrolled dental infection, spread of infection from other local structures (tonsils, vertebrae), local IV catheter placement or injection drug use, diabetes, HIV infection, and local trauma (e.g., the use of laryngeal mask anesthesia).^{3,4} A poor level of education and living far from a tertiary care center have also been shown to increase the risk of development of severe deep neck space infection.⁵

CLINICAL SYNDROMES

Sinusitis

Acute bacterial sinusitis accounts for a high proportion of physician visits in the primary care setting.⁶ In the ICU, patients who are critically ill, with nasogastric, endotracheal, or nasotracheal tubes in place, may develop acute sinusitis caused by resistant nosocomial organisms (e.g., methicillin-resistant *S. aureus* [MRSA], *P. aeruginosa*) and anaerobes.⁷ Treatment involves the use of broad-spectrum antimicrobial agents (Table 126-2) and close collaboration with an otolaryngologist to determine if drainage is needed. In addition, application of topical vasoconstrictors and steroids to the nasal mucosa is often recommended to help the sinus secretions drain.

Complications of nosocomial sinusitis are related to the local anatomy. Spread via the diploic veins can result in meningitis, brain abscess, contiguous osteomyelitis, or cavernous sinus thrombosis. Spread from the ethmoid sinuses can result in frontal lobe brain abscesses, whereas sphenoid sinus infection can spread to involve the surrounding pituitary gland, optic chiasm, internal carotid artery, cavernous sinus, or temporal lobe of the brain.¹

In patients with diabetic ketoacidosis, high-dose steroid treatment, severe neutropenia, or history of desferrioxamine treatment, rhinocerebral mucormycosis or aspergillosis can develop. This infection can be rapidly fatal if the underlying problem cannot be corrected. The general teaching has been that high-dose antifungal therapy (see Table 126-2) plus extensive surgery is always required for any hope of survival. However, the need for major surgery in all cases has come into question recently.⁸ Close collaboration with appropriate surgeons and infectious disease colleagues is required in such cases.

Pharyngeal Infections

Life-threatening pharyngeal infections include acute anaerobic pharyngitis (Vincent's angina) caused by a combination of oral anaerobes and spirochetes. The clinical manifestations of this entity in the critically ill host include acute ulcerations and necrosis of the oral mucosa and gums. Secondary bacteremia with sepsis syndrome can complicate matters. Treatment involves adequate oral debridement and administration of antibiotics with both aerobic and anaerobic activity (see Table 126-2).¹

Quinsy (peritonsillar abscess) can complicate previous tonsillitis and is most common among young adults. Presenting symptoms include fever, pharyngeal pain, and unilateral pharyngeal swelling. If not adequately drained, the infection can spread into the lateral pharyngeal space, which was the most common cause of quinsy-related mortality in preantibiotic days. Infection with anaerobes can result in a higher rate of recurrence of quinsy.⁶ *Fusobacterium necrophorum* is currently the most commonly encountered organism in peritonsillar abscesses in Denmark.⁹

Recurrent bouts of tonsillitis (five or more) in patients aged under 30 years have been noted to be a risk factor for development of peritonsillar abscess.¹⁰

Diphtheria is now rare thanks to mass vaccination. It presents as a sharply demarcated adherent dark gray nasal or pharyngeal membrane. Clinical illness is caused by the release of a bacterial toxin that inhibits translocase (via inhibition of elongation factor 2). Myocardial

dysfunction and central nervous system toxin-mediated injury may occur late, but fulminant infections can be complicated by death from acute respiratory obstruction or circulatory failure (bull-neck diphtheria).¹ Culture of the organism (*Corynebacterium diphtheriae*) requires the use of a specific Loeffler medium.

Epiglottitis

Acute epiglottitis is primarily a disease of children who have not received the *Haemophilus influenzae* type b (Hib) vaccine and is thus rare at present.¹¹ Acute epiglottitis presents as an acute febrile illness

usually of less than 12 hours' duration, with the child characteristically sitting forward, drooling saliva, and taking shallow and apprehensive breaths (deeper breathing draws the epiglottis over the airway and produces obstruction). The diagnosis is made clinically, although lateral neck radiography (if the child is stable enough to go for x-ray) characteristically shows enlargement of the epiglottis 30% to 57% of the time. Attempts to visualize the classically described edematous cherry-red epiglottis directly may precipitate acute airway obstruction and should not be attempted unless the ability to secure an airway immediately is certain. Blood and epiglottis cultures usually grow *H. influenzae* type b. However, since the introduction of mass vaccination against *H. influenzae* type b, the incidence of infection with non-type b strains is increasing.¹¹

Antibiotic options for epiglottitis are outlined in Table 126-2. There is no clear consensus on the role of exogenous corticosteroids to decrease epiglottic edema. Rifampin prophylaxis should be administered for 4 days to close household and hospital contacts of patients (especially those younger than 4 years) with invasive *H. influenzae* type b disease.

Retropharyngeal Infections

The area situated between the pharynx anteriorly and the vertebrae posteriorly constitutes the retropharyngeal space, which begins behind the pharynx and ends at the junction of the cervical and thoracic vertebrae (see Table 126-1). The space is subdivided into several distinct anatomic spaces (retropharyngeal, prevertebral, "danger space"), some of which may provide the means of spread of infection from the initial retropharyngeal area to distant sites.¹²

Located between the prevertebral space posteriorly and the retropharyngeal space anteriorly is a potential space called the "danger space," which connects the base of the skull with the posterior mediastinum and diaphragm. Infection may spread unimpeded within this space. In addition, infection occurring between the vertebrae and the prevertebral fascia may spread along the length of the vertebral column.

Infections of the retropharynx occur either as:

- Primary infections
- Secondary to extension posteriorly from the pharynx or anteriorly from infected cervical vertebrae
- Via hematogenous spread

TABLE 126-1 Differentiating Features of Deep Neck Infections

| SPACE | CLINICAL FEATURES* |
|--|---|
| Submandibular space (Ludwig's angina) | Woody submental induration, protruding swollen/necrotic tongue, no trismus, rotted lower molars commonly present |
| Lateral pharyngeal space (anterior) | Fever, toxicity, trismus, neck swelling |
| Lateral pharyngeal space (posterior) | No trismus, no swelling (unless ipsilateral parotid is involved), cranial nerve IX-XII palsies, Horner's syndrome, carotid artery erosion |
| Retropharyngeal space (retropharynx) | Neck stiffness, decreased neck range of motion, soft-tissue bulging of posterior pharyngeal wall, sore throat, dysphagia, dyspnea |
| Retropharyngeal space ("danger space") | Mediastinal or pleural involvement |
| Retropharyngeal space (prevertebral) | Neck stiffness, decreased neck range of motion, cervical instability, possible spread along length of vertebral column |
| Jugular vein septic thrombophlebitis (Lemierre syndrome) | Sore throat, swollen tender neck, dyspnea, chest pain, septic arthritis |

*Fever and signs of systemic toxicity are common to all.

TABLE 126-2 Therapeutic Options for Sinusitis, Pharyngitis, Epiglottitis

| SYNDROME | LIKELY FLORA | ANTIBIOTIC OPTIONS* |
|--------------------------------|--|---|
| Sinusitis (community acquired) | <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> | Ampicillin-sulbactam (3 g IV q 6 h) Levofloxacin (500 mg IV q 24 h) or moxifloxacin (400 mg IV q 24 h) Levofloxacin (500 mg IV q 24 h) plus clindamycin (300-900 mg IV q 8 h) or moxifloxacin (400 mg IV q 24 h) |
| Sinusitis (ICU acquired) | <i>Pseudomonas aeruginosa</i> , <i>Escherichia coli</i> and related coliforms, methicillin-resistant <i>S. aureus</i> (MRSA) | Ceftazidime (2 g IV q 8 h) or piperacillin-tazobactam (3.375 g IV q 4 h) plus an aminoglycoside, plus vancomycin (1 g IV q 12 h) |
| Sinusitis (fungal) | <i>Aspergillus</i> spp. <i>Mucorales</i> spp. | Amphotericin B (1-1.5 mg/kg/d IV) Liposomal amphotericin B (5-10 mg/kg/d IV) Voriconazole (6 mg/kg q 12 h × 2 doses, then 4 mg/kg q 12 h) Caspofungin (70 mg IV day 1, then 50 mg/d IV) Itraconazole (200 mg IV q 12 h × 4 doses, then 200 mg/d IV) |
| Pharyngitis | <i>Corynebacterium diphtheriae</i> Epstein-Barr virus (with airway compromise) | IV penicillin or erythromycin plus diphtheria antitoxin No antiviral therapy effective IV steroids |
| Epiglottitis | <i>H. influenzae</i> type b <i>Streptococcus pyogenes</i> (group A strep) | Ceftriaxone (1-2 g IV q 24 h) Ampicillin-sulbactam (3 g IV q 6 h) Rifampin prophylaxis (600 mg orally q 24 h) for close contacts for 4 days |

*Antibiotic choices listed are examples, since for most infections, multiple different antibiotics are effective; individual choice will be influenced by patient factors (e.g., allergies), local hospital bacterial resistance rates, and microbiological culture results.

Clinically, retropharyngeal infections present with acute fever, systemic toxicity, sore throat, neck stiffness, dysphagia, and dyspnea. Airway obstruction may occur as a consequence of anterior bulging of the pharyngeal wall with supraglottic compression.

Prevertebral infections usually involve the cervical vertebrae and present with neck pain and stiffness and prevertebral soft-tissue swelling. Rarely, instability or destruction of the cervical vertebrae may develop, with death due to acute spinal cord compression.

Danger-space infection is suspected when pleural or mediastinal infection or pain complicates a retropharyngeal infection.¹² Mediastinitis secondary to danger-space infection is generally fulminant, with pleural extension and a high mortality rate. Rarely, mediastinal infections, such as may occur after coronary artery bypass graft surgery, may spread upward through the danger space and present in the retropharynx.

The bacteriology of retropharyngeal infections is that of mixed aerobic/anaerobic oral bacteria. In the critically ill host with nosocomial infection, colonization of the oropharynx with resistant pathogens will necessitate modification of antimicrobial coverage. The imaging techniques needed include plain lateral neck x-rays that will show loss of normal cervical lordosis as well as thickening of the retrotracheal area (usually <22 mm) or of the prevertebral fascia (usually <7 mm). Bedside ultrasonography may provide information regarding the presence or absence of drainable collections, but if the patient is stable enough to go to the radiology suite, computed tomography (CT) or magnetic resonance imaging (MRI) scans provide the best definition studies.¹³ The presence of a hypodense mass with rim irregularity on a contrast-enhanced CT scan is highly suggestive. Close collaboration with appropriate surgical colleagues is necessary for successful management.¹² Therapy is outlined in Table 126-3. On occasion, non-bacterial processes such as Kawasaki disease can mimic retropharyngeal abscesses.¹⁴

Submandibular Space Infection (Ludwig's Angina)

The submandibular space is contained between the mucous membranes of the floor of the mouth superiorly and the muscle and fascia attachments of the hyoid bone inferiorly. The most common route of infection into this space is via infected lower molar teeth, and infection is more common in persons with underlying diabetes, neutropenia, or systemic lupus erythematosus.

Clinical presentation of submandibular space infection is that of an acutely ill patient with mouth pain, dysphagia, drooling of saliva, stiff neck, and fever. The submandibular tissues are "woody," not fluctuant, and true drainable collections are uncommon. The tongue may be swollen and displaced upward against the palate and also protrude out of the mouth. Trismus is not present; however, if the infection spreads to the lateral pharyngeal space, trismus may occur. Unrecognized lateral pharyngeal space involvement may be complicated by subsequent spread to the retropharyngeal space. Late complications of Ludwig's angina include death from airway obstruction, aspiration pneumonia, carotid artery erosion, and tongue necrosis.¹⁶

Lateral neck x-rays will demonstrate edema of the submandibular soft tissues. Pockets of gas may be seen if gas-forming organisms are involved. CT scanning is most helpful diagnostically. However, attention must be paid to having qualified staff accompany the patient to the CT scanner in case acute airway obstruction develops. Should airway protection be needed, tracheotomy or cricothyroidotomy is advocated because of the risk of inducing acute airway obstruction with routine "blind" nasal or oral intubation. The infection is commonly polymicrobial, and appropriate antibiotic therapy options are described in Table 126-3. In approximately 50% of cases, surgical drainage is required. In addition, causative rotted molar teeth (if present) should be removed.¹⁶

Lateral Pharyngeal Space Infections

Infection of the lateral pharyngeal space is one of the most common deep neck infections encountered. In a review of 110 deep neck infections in adults seen at an academic medical center over a 10-year period, infections of the lateral pharyngeal space accounted for 55%.¹⁶ In contrast, such infections are rare in children, with peritonsillar infection (quinsy) being the most common deep neck infection.

The lateral pharyngeal space is cone shaped, extending from the sphenoid bone down to the hyoid bone. Posteriorly, it is bound by the prevertebral fascia (that separates it from the retropharyngeal space) and anteriorly by the buccinator and superior constrictor muscles. The parotid gland communicates with this space. The styloid process divides the space into an anterior compartment (containing fat, lymph nodes, and muscle) and a posterior compartment (containing the carotid artery, cranial nerves IX–XII, and the cervical sympathetic trunk).

TABLE 126-3 Therapeutic Options for Deep Neck Infections

| SYNDROME | LIKELY FLORA | THERAPEUTIC OPTIONS* |
|--|---|---|
| Submandibular space infection (community acquired) | Anaerobes, streptococci, <i>Staphylococcus aureus</i> | Ampicillin-sulbactam (3 g IV q 6 h) Ceftriaxone (1–2 g IV q 24 h) <i>plus</i> clindamycin (300–900 mg IV q 8 h) <i>or</i> metronidazole (500 mg IV q 6 h) Ertapenem (1 g IV q day) |
| Submandibular space infection (hospital/ICU acquired) | <i>Pseudomonas aeruginosa</i> , methicillin-resistant <i>S. aureus</i> (MRSA), anaerobes | Imipenem (500 mg IV q 6 h) <i>or</i> piperacillin-tazobactam (3.375 g IV q 8 h by continuous infusion) <i>plus</i> vancomycin (1 g IV q 12 h) ¹⁵ |
| Retropharyngeal space infection | Anaerobes, streptococci, <i>S. aureus</i> | Ampicillin-sulbactam (3 g IV q 6 h) Ceftriaxone (1–2 g IV q 24 h) <i>plus</i> clindamycin (300–900 mg IV q 8 h) <i>or</i> metronidazole (500 mg IV q 6 h) Ertapenem (1 g IV q day) |
| Lateral pharyngeal space infection | Anaerobes, streptococci, <i>S. aureus</i> | Ampicillin-sulbactam (3 g IV q 6 h) Ceftriaxone (1–2 g IV q 24 h) <i>plus</i> clindamycin (300–900 mg IV q 8 h) <i>or</i> metronidazole (500 mg IV q 6 h) Ertapenem (1 g IV q day) |
| Internal jugular vein septic thrombophlebitis | <i>Fusobacterium necrophorum</i> | Metronidazole (500 mg IV q 6 h) Clindamycin (300–900 mg IV q 8 h) Ampicillin-sulbactam (3 g IV q 6 h) |

*Antibiotic choices listed are examples, since for most infections, multiple different antibiotics are effective; individual choice will be influenced by patient factors (e.g., allergies, concurrent medications), local hospital bacterial resistance rates, and microbiological culture results.

Common precipitating causes of lateral pharyngeal space infection include dental disease (33%), injection drug use (inserting needles directly into the space) (20%), local trauma (9%), and tonsillitis (4%). Patients frequently have underlying diabetes or human immunodeficiency virus (HIV) infection.

Clinically, anterior lateral pharyngeal space infections present with fever, pain, trismus, and systemic toxicity. Turning the head to the opposite side causes increased pain due to stretching of the ipsilateral sternocleidomastoid muscle.

Infection of the posterior lateral pharyngeal space presents differently from infections involving the anterior pharyngeal space. Common symptoms include fever, systemic toxicity, and parotid swelling. Trismus and external swelling do not occur. Involvement of local vital structures can occur, including carotid artery erosion or clot, septic thrombophlebitis of the internal jugular vein, cranial nerve IX–XII palsies, or Horner's syndrome.

Therapy involves urgent surgical intervention to drain purulent material and prevent spread of infection to the retropharyngeal space or erosion of the carotid artery. The choice of antibiotics for this frequently polymicrobial infection is shown in Table 126-3.

Descending Necrotizing Mediastinitis

Rapid downward spread of deep neck infections can result in the development of necrotizing soft-tissue infections of the chest wall and mediastinum. A recent study of 45 such cases collected over a 12-year period demonstrated that they tended to develop as a complication of dental or deep neck polymicrobial infections, affecting persons aged 40 to 60 years most commonly. Mixed aerobic/anaerobic flora was the rule, and risk factors included alcoholism and diabetes mellitus. Mortality was around 15% to 20%.¹² Death may be sudden due to medical complications of the infectious process.¹⁷

Internal Jugular Vein Septic Thrombophlebitis (Lemierre Syndrome)

Septic thrombophlebitis of the internal jugular vein is known as *Lemierre syndrome*. This relatively rare entity is usually caused by infection with the anaerobe *Fusobacterium necrophorum*, a normal inhabitant of the human gingival crevice. Latest theories on the pathogenesis of this infection indicate that the first stage of infection is pharyngitis in approximately 87% of cases. Recent data suggest that *F. necrophorum* causes pharyngitis in young adults aged 15 to 24 years as frequently as *Streptococcus pyogenes*.⁹ This infection is then followed by invasion of the lateral pharyngeal space, with development of septic thrombophlebitis of the internal jugular vein.¹⁸ Subsequently, bloodstream infection develops, with the classic findings of septic pulmonary emboli or cavitating pneumonia and septic arthritis. Other precipitating factors

include mastoiditis, lateral pharyngeal space infection, and trauma to the internal jugular vein.

Clinically, Lemierre syndrome begins with fever and sore throat. When internal jugular vein involvement develops, patients complain of a swollen and/or tender neck, which is thus a warning sign of danger in a patient with recent pharyngitis. Dyspnea and pleuritic chest pain indicate pulmonary involvement.

Early diagnosis is critical to minimize the risk of infectious metastatic complications requiring surgical intervention or drainage. Blood cultures should be promptly obtained and empirical antianaerobic bacterial coverage begun. Radiologic diagnosis is made most reliably by CT scanning, although bedside ultrasound examination of the internal jugular vein can be useful in the critically ill patient who cannot leave the ICU. If the infection occurs secondary to mastoiditis, it is necessary to rule out intracerebral vein thrombosis by MRI scanning. The patient may also develop secondary complications such as carotid artery thrombosis or parotid gland infection with abscess formation.¹⁹

Antibiotic choices are outlined in Table 126-3. There are no firm data to support or refute the use of anticoagulants in Lemierre syndrome.²⁰ In addition, surgical ligation or excision of the internal jugular vein for uncontrollable sepsis was necessary in approximately 8% of cases in a recently published series of cases.²⁰ MRSA has recently been shown to cause Lemierre syndrome, especially in injection drug users or patients with the infection developing as a complication of venous cannulation.²¹

CONCLUSION

The intensivist will frequently be asked to assist in the care of patients with serious deep neck infections. Critical issues encountered include protection of the airway, sepsis management, and the potential for erosion of the infection into surrounding vital structures in the neck. Such infections are frequently polymicrobial in nature; thus, broad-spectrum antibiotics with both aerobic and anaerobic coverage should be chosen.

Common issues to be decided for each patient individually include the following:

- The safety of performing an intraoral examination given the risk of precipitating acute airway obstruction.
- The safety of sending a patient out of the ICU for studies such as CT scanning. Although patients may appear stable initially, they are at risk for sudden development of acute airway obstruction and thus should always be accompanied by a team capable of securing an airway when they travel out of the ICU for tests or procedures.
- The need for and timing of possible surgical intervention. Early close collaboration with otolaryngologists, head and neck surgeons, neurosurgeons, or vascular surgeons is critical for successful management of these complex and frequently critically ill patients.

Many immunocompromised patients are managed in intensive care units (ICUs) every year, with infection being a leading cause of ICU admission. Common examples of such infections include community-acquired pneumonia, bacteremia, and central nervous system (CNS) infections. The incidence of infections acquired by immunocompromised patients during ICU admissions is also significant.¹ Mortality from certain infections in immunocompromised patients exceeds 50%.² Early diagnosis, initiation of appropriate antimicrobial and supportive therapy, and reduction in immunosuppression where possible can improve outcomes significantly.

COMMONLY ENCOUNTERED IMMUNOCOMPROMISING CONDITIONS

Immunocompromise can be broadly defined as a state in which the response of the host to a foreign antigen is subnormal. It can be congenital (primary) or acquired. Congenital immunodeficiencies are now much less common than acquired immunodeficiencies. In general, congenital immunodeficiency is observed more frequently in patients in pediatric ICUs than in those in adult ICUs. Patients with congenital immunodeficiencies usually have repeated infections, especially infections affecting the sinuses and lower respiratory tract. Congenital immunodeficiencies are usually “pure,” in that the defects in the host response to foreign antigens are usually specific and well defined. For example, Bruton’s X-linked agammaglobulinemia is associated with a defect in the normal maturation process of immunoglobulin-producing B cells. As a result, mature circulating B cells, plasma cells, and serum immunoglobulin are absent. The patient is susceptible to organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*, normally dealt with by immunoglobulins. Other congenital immunodeficiency syndromes are listed in Table 127-1.

Most immunocompromised patients managed in adult ICUs have acquired immunocompromise. Although the response of host defenses in the elderly, diabetics, and alcoholics is compromised, this chapter deals primarily with four categories of immunocompromised patients: (1) patients receiving chemotherapy for hematologic malignancies and solid tumors; (2) patients receiving immunosuppressive therapy in the context of solid organ transplantation; (3) patients receiving corticosteroids, methotrexate, monoclonal antibodies to tumor necrosis factor, and other disease-modifying agents for rheumatoid arthritis, Crohn’s disease, and autoimmune disorders; and (4) patients with human immunodeficiency virus (HIV) infection.

Hematologic Malignancies and Solid Tumors

Prolonged neutropenia from chemotherapy carries a significant risk of bacterial and fungal infection. Classically, gram-negative organisms such as *Pseudomonas aeruginosa* and fungal organisms such as *Aspergillus* species have been associated with severe neutropenia. It has long been known that the severity and duration of neutropenia influence the risk of infection.³ It has also been well established that aggressive chemotherapy and radiotherapy for Hodgkin’s disease coupled with splenectomy significantly impair humoral defense against encapsulated organisms such as *S. pneumoniae*, *H. influenzae*, and *Neisseria meningitidis*.⁴ Stem cell transplantation (particularly allograft transplantation) is associated with a substantial risk of graft-versus-host disease (GVHD). Prophylaxis and treatment for GVHD may involve use of

drugs such as cyclosporine or tacrolimus plus corticosteroids. Cyclosporine and tacrolimus inhibit calcineurin, an enzyme important in the lymphocyte activation cascade. Corticosteroids also affect lymphocyte function and depress functions of activated macrophages. As a result, patients receiving therapy for GVHD may be prone to fungal, viral, and mycobacterial infections, in addition to bacterial infections associated with prolonged neutropenia.

Solid Organ Transplantation

Solid organ transplant recipients are uniquely susceptible to infection.⁵ They undergo significant surgery, breaching the defenses provided by the skin. Furthermore, they remain in ICUs for prolonged periods of time, requiring intravenous access and mechanical ventilation—here, cutaneous and pulmonary barriers to infection are breached. Finally, solid organ transplant recipients receive immunosuppressive therapy to prevent graft rejection. The commonly used immunosuppressive medications are listed in Table 127-2. Immunosuppressive regimens are in a constant state of flux—more recent trends have been toward aggressive “pretreatment” immediately before transplantation, coupled with decreased immunosuppression in the posttransplant period.⁶

In the early posttransplant period, transplant recipients are susceptible to nosocomially acquired bacterial infections such as pneumonia, catheter-related bloodstream infection associated with general ICU care, and wound and intraabdominal infections associated with surgical procedures. Opportunistic infections may be acquired from the organ graft; cytomegalovirus (CMV) is the most pertinent example,⁷ but a wide variety of infections (e.g., rabies, histoplasmosis, tuberculosis, and West Nile virus) have also been acquired from grafts. Solid organ transplant recipients, by virtue of their iatrogenic immunosuppression, are also susceptible to reactivation of latent infection (e.g., CMV infection, tuberculosis, or histoplasmosis) or to infections acquired through the hospital environment (e.g., aspergillosis, legionellosis, or tuberculosis).

Rheumatoid Arthritis and Autoimmune Disorders

Therapy for rheumatoid arthritis and other autoimmune disorders may be with simple analgesics or nonsteroidal antiinflammatory drugs. Drugs with the potential to cause significant immunocompromise are also frequently used. Classically, therapy has been with corticosteroids or disease-modifying antirheumatic drugs such as azathioprine, cyclosporine, penicillamine, gold salts, hydroxychloroquine, leflunomide, methotrexate, or sulfasalazine. The effects of corticosteroids, azathioprine, and cyclosporine on host defenses have been noted previously (see Table 127-2). Methotrexate reversibly inhibits dihydrofolate reductase and interferes with DNA synthesis and repair and cellular replication. In addition to its use in rheumatoid arthritis, it can be used as an antineoplastic agent. Methotrexate, however, can cause significant neutropenia, and low-dose methotrexate is generally less likely to increase the infection risk in patients with rheumatoid arthritis.^{8,9}

A variety of “biologic” agents have become available for rheumatoid arthritis (Table 127-3). The biologics may also be used in treatment of Behçet’s disease, Crohn’s disease, GVHD, hairy cell leukemia, psoriasis, pyoderma gangrenosum, sarcoidosis, and ulcerative colitis. Considerable attention has been paid to the possibility of tuberculosis

TABLE 127-1 Congenital (Primary) Causes of Immunodeficiency

| CONDITION (IMMUNODEFICIENCY) | ORGANISMS WITH INCREASED TENDENCY TO CAUSE INFECTION IN THIS CONDITION |
|--|--|
| T-LYMPHOCYTE DEFICIENCIES | |
| DiGeorge syndrome (thymic aplasia with reduced CD4 and CD3 cells) | Viruses (especially HSV and measles), sometimes <i>Pneumocystis jirovecii</i> , fungi, or gram-negative bacteria |
| Purine nucleoside phosphorylase deficiency (marked T-cell depletion) | <i>P. jirovecii</i> and viruses |
| B-LYMPHOCYTE DEFICIENCIES | |
| Bruton's X-linked agammaglobulinemia (absence of B cells, plasma cells, and antibody) | <i>Haemophilus influenzae</i> , <i>Streptococcus pneumoniae</i> , <i>Staphylococcus aureus</i> , <i>Pseudomonas aeruginosa</i> , <i>P. jirovecii</i> (after the first 4-6 months of life when maternal antibody has been consumed) |
| Selective IgG subclass deficiencies | Variable |
| Selective IgA deficiency | <i>S. pneumoniae</i> , <i>H. influenzae</i> |
| Hyper-IgM immunodeficiency (elevated IgM but reduced IgG and IgA) | <i>S. pneumoniae</i> , <i>H. influenzae</i> , <i>P. jirovecii</i> (rarely) |
| MIXED T- AND B-LYMPHOCYTE DEFICIENCIES | |
| Common variable immunodeficiency (leads to various B-cell activation or differentiation defects and gradual deterioration of T-cell number and function) | <i>S. pneumoniae</i> , <i>H. influenzae</i> , CMV, VZV, <i>P. jirovecii</i> |
| Severe combined immunodeficiency (severe reduction in IgG and absence of T cells) | <i>P. jirovecii</i> , viruses, <i>Legionella</i> |
| Wiskott-Aldrich syndrome (decreased T-cell number and function, low IgM, occasionally low IgG) | <i>S. pneumoniae</i> , <i>H. influenzae</i> , HSV, <i>P. jirovecii</i> |
| Ataxia-telangiectasia (decreased T-cell number and function; IgA, IgE, IgG ₂ , and IgG ₄ deficiency) | <i>S. aureus</i> , <i>S. pneumoniae</i> , <i>H. influenzae</i> |
| DISORDERS OF COMPLEMENT | |
| C3 deficiency (congenital absence of C3 or consumption of C3 due to deficiency of C3b inactivator) | <i>S. pneumoniae</i> , <i>H. influenzae</i> , enteric gram-negative bacilli |
| PHAGOCYTE DEFECTS | |
| Chronic granulomatous disease (defect in NADPH oxidase in phagocytic cells) | <i>S. aureus</i> , <i>Escherichia coli</i> , <i>Klebsiella pneumoniae</i> , <i>Enterobacter cloacae</i> , <i>S. marcescens</i> , <i>P. aeruginosa</i> , <i>Aspergillus</i> |
| Chédiak-Higashi syndrome (impaired microbicidal activity of phagocytes) | <i>S. aureus</i> , <i>H. influenzae</i> , <i>Aspergillus</i> |
| Kostmann syndrome, Shwachman-Diamond syndrome, cyclic neutropenia (low neutrophil count) | <i>S. aureus</i> , enteric gram-negative bacilli, <i>P. aeruginosa</i> |

CMV, cytomegalovirus; HSV, herpes simplex virus; Ig, immunoglobulin; NADPH, nicotinamide adenine dinucleotide phosphate; VZV, varicella-zoster virus.

TABLE 127-2 Immunosuppressive Drugs Used in Solid Organ Transplantation and Their Mechanisms of Activity

| IMMUNOSUPPRESSIVE | MODE OF ACTION |
|---------------------------|--|
| Corticosteroids | Negative regulation of cytokine gene expression |
| Azathioprine | Inhibits DNA and RNA synthesis; inhibits T- and B-cell function |
| Cyclosporine | Calcineurin inhibitor; inhibits cytokine expression |
| Tacrolimus | Calcineurin inhibitor; inhibits cytokine expression |
| Sirolimus (rapamycin) | Prevents translation of mRNAs encoding cell cycle regulators |
| Mycophenolate mofetil | Blocks purine biosynthesis; inhibits T- and B-cell proliferation |
| Polyclonal antilymphocyte | Lymphocyte depletion antibodies (e.g., Atgam, Thymoglobulin) |
| Muromonab-CD3 (OKT3) | Anti-CD3 monoclonal antibody |
| Alemtuzumab (Campath) | Anti-CD52 monoclonal antibody |
| Daclizumab, basiliximab | Anti-CD25 monoclonal antibody |

TABLE 127-3 Commonly Used Anticytokines for Management of Rheumatoid Arthritis

| DRUG | MECHANISM OF ACTION | FDA-APPROVED INDICATIONS |
|-----------------------|---|--|
| Adalimumab (Humira) | Recombinant, fully human anti-TNF monoclonal antibody | Ankylosing spondylitis Crohn's disease Psoriatic arthritis Rheumatoid arthritis |
| Anakinra (Kineret) | Recombinant human interleukin-1 receptor antagonist | Rheumatoid arthritis |
| Etanercept (Enbrel) | TNF receptor p75 Fc fusion protein | Ankylosing spondylitis Juvenile rheumatoid arthritis Plaque psoriasis Psoriatic arthritis Rheumatoid arthritis |
| Infliximab (Remicade) | Chimeric monoclonal antibody to TNF | Ankylosing spondylitis Crohn's disease Psoriatic arthritis Plaque psoriasis Rheumatoid arthritis Ulcerative colitis |
| Tocilizumab (Actemra) | IL-6 receptor-inhibiting monoclonal antibody | Rheumatoid arthritis |

FDA, U.S. Food and Drug Administration; IL-6, interleukin 6; TNF, tumor necrosis factor.

developing after treatment with such agents.¹⁰ The risk is sufficiently high that it is recommended that tuberculin skin testing or interferon gamma (IFN- γ) release assays be performed to detect latent tuberculosis before the initiation of anticytokine agents. Invasive infections with *Histoplasma*, *Candida*, *Pneumocystis jirovecii*, *Aspergillus*, *Cryptococcus*, *Nocardia*, *Salmonella*, *Listeria*, *Brucella*, *Bartonella*, nontuberculous mycobacteria, *Leishmania*, and *Toxoplasma* have also been reported to be associated with the use of these medications.^{11–14} As is the case with transplant-associated immunocompromise, these infections may represent reactivation of latent infection or new acquisition of organisms through environmental exposure.

Human Immunodeficiency Virus Infection

HIV infection remains a relatively common infection, but acquired immunodeficiency syndrome (AIDS) has become less frequently encountered in ICUs since the advent of highly active antiretroviral therapy. A decline in CD4 counts creates a predisposition to *P. jirovecii* pneumonia, mycobacterial infection, fungal infection (e.g., cryptococcal meningitis), and viral infection (e.g., CMV infection). Many patients with HIV infection are co-infected with hepatitis C virus, and as a result, liver failure is now a relatively common reason for ICU admission in HIV-infected patients. In some centers, liver transplantation is performed in HIV-infected patients with hepatitis virus–induced liver diseases.^{15,16}

GENERAL DIAGNOSTIC APPROACH TO IMMUNOCOMPROMISED PATIENTS WITH SEVERE INFECTIONS

Immunocompromised patients are a heterogeneous group. The infections commonly encountered by a patient with neutropenia as a consequence of chemotherapy may be different from infections observed in a patient with rheumatoid arthritis who is receiving infliximab. Even within a particular category, different renal transplantation recipients, for example, may have a different degree of immunocompromise and a different susceptibility to infection. In solid organ transplant recipients, the “net state of immunosuppression” (i.e., the cumulative burden of immunosuppression with a special weighting toward recent T-cell ablative therapy) influences the risk of infection. A renal transplant recipient who is receiving tacrolimus monotherapy twice per week would be less susceptible to opportunistic infection than a patient with recent acute cellular rejection who is receiving OKT3 or alemtuzumab. There have been more recent attempts to quantify immune function in solid organ transplant recipients,¹⁷ although it has not yet been definitively proved that such tests predict infection risk. In contrast, with HIV infection, CD4 lymphocyte count and HIV RNA quantification (“viral load”) predict risk of infection.¹⁸ Patients with CD4 counts greater than 500 are unlikely to be infected with an opportunistic pathogen, whereas those with CD4 counts of 200 to 500 may be infected with organisms such as *Mycobacterium tuberculosis*, but they are unlikely to be infected with opportunistic pathogens such as CMV or *M. avium* complex. Patients with CD4 counts less than 200 have an increased risk of a wide variety of opportunistic infections.

Specific environmental exposures may be potentially important for immunocompromised patients. A travel history to the deserts of the southwestern United States and northern Mexico, for example, may increase the likelihood that an immunocompromised patient has coccidioidomycosis¹⁹; histoplasmosis is endemic in the Ohio River valley.²⁰ Alternatively, there may be environmental risks within the ICU. Outbreaks of invasive pulmonary aspergillosis have been linked to construction activity within the hospital. Outbreaks of legionellosis may be waterborne via air conditioning cooling units, drinking water, or aerosolization from showers.²¹ Furthermore, it is possible that many fungal and bacterial infections are waterborne.^{22,23} Tuberculosis transmission has been well described in ICUs caring for transplant recipients or HIV-infected patients.²⁴ In summary, the net state of immunosup-

pression must be considered in the context of recent environmental exposures.

Although elements of history taking and physical examination may narrow the differential diagnosis of the causative agent of infection in immunocompromised patients, some of the “rules” applied to diagnosis in immunocompetent patients do not apply. Caution must be exercised in use of the diagnostic principle that follows Occam’s razor: “entities are not to be multiplied without necessity.” In an immunocompetent patient, given all the patient’s symptoms, signs, and noninvasive laboratory test results, one unifying diagnosis usually explains all. In contrast, immunocompromised patients may have more than one infection at any given time. A neutropenic patient may have bacterial pneumonia and invasive pulmonary aspergillosis simultaneously, whereas an immunocompromised patient with HIV infection may have *P. jirovecii* pneumonia and pulmonary infiltrates due to human herpesvirus (HHV)-8 infection (Kaposi sarcoma).

The potential for multiple diagnoses underscores the need for early invasive testing in immunocompromised patients with severe infection. Patients with unexplained severe community-acquired pneumonia may be best managed by early bronchoalveolar lavage performed before antimicrobial therapy has commenced. Bronchoalveolar lavage could be sent for Gram stain, Ziehl-Neelsen stain, modified acid-fast stain, calcofluor stain, direct fluorescent antibody tests, polymerase chain reaction (PCR), and cytologic analysis to enable rapid diagnosis of infection with bacteria, mycobacteria, *Nocardia*, fungi, *Legionella*, CMV, community-acquired respiratory viruses, and *P. jirovecii*. The bronchoalveolar lavage should be inoculated onto solid media, and molecular diagnostic testing should be used as appropriate. An outline of the diagnostic approach in immunocompromised patients is given in [Box 127-1](#).

MAJOR MANIFESTATIONS OF INFECTION IN IMMUNOCOMPROMISED PATIENTS

The organism causing infection in an immunocompromised patient sometimes can be inferred by the specific host defect in the immunologic defense or the specific clinical manifestation. In most circumstances, the differential diagnosis is too broad, however, for making a definitive clinical diagnosis.

Pulmonary Infection

Pneumonia is a significant cause of morbidity and mortality in immunocompromised patients. In contrast to a normal host, the impaired responsiveness of the immune system means that the disease presents in unusual ways, which may lead to challenges in establishing a diagnosis.

Infectious microorganisms usually gain access to the respiratory tract through inhalation, although hematogenous spread sometimes may occur. Mechanical defenses remove the bulk of potentially harmful agents from the lungs ([Table 127-4](#)); inhaled particles greater than 10 μm in diameter usually become trapped in the upper airways or are removed by coughing or mucociliary clearance. Most bacteria range from 0.5 to 2 μm in size and are able to reach the terminal airways/alveoli and potentially cause infection. In the alveoli, the alveolar macrophages are the first line of defense. Subsequently, an inflammatory response consisting of polymorphonuclear neutrophils is important. Finally, specific T-cell and B-cell immune responses are essential for successful defense against many pathogens.

As noted earlier, although it may be possible to pinpoint a major immunologic deficiency, most immunocompromised individuals have an assortment of deficiencies in host defenses working together. An organ transplant recipient may be intubated, have multiple intravenous lines, be diabetic, and be on corticosteroids and tacrolimus. All these factors contribute to the overall degree of immunity, each paving the way for its own peculiar array of susceptibilities to pulmonary

BOX 127-1

Diagnostic Approach for Severe Infections in Immunocompromised Patients

HISTORY TAKING AND REVIEW OF PRIOR RECORDS

Likely degree of immunocompromise

Recent CD4 lymphocyte count and HIV viral load

Time since transplantation

Recent acute cellular rejection or GVHD and treatment thereof

Current or recent receipt of immunosuppressive medications

Current or recent receipt of antiretroviral medications

Prophylaxis against opportunistic infections

Receipt of antimicrobial prophylaxis against *Pneumocystis jirovecii*, HSV, or CMV

Vaccination status (pneumococcus, influenza, *Neisseria meningitidis*)

Family history

Personal or family history of tuberculosis or chickenpox

Potential environmental exposures

Travel history to southwestern United States

Exposure to hospital construction activity (aspergillosis)

Exposure to hospital water supply (legionellosis, aspergillosis)

Exposure to patients with tuberculosis or chickenpox

Donor and recipient serostatus for CMV or *Toxoplasma gondii*

PHYSICAL EXAMINATION

Skin

Presence of cutaneous nodules consistent with cryptococcosis or nocardiosis

Presence of cutaneous manifestations of GVHD

Kaposi sarcoma

Line insertion site erythema or pus

Peripheral embolic phenomena

Scars consistent with prior surgery

Mouth and other mucous membranes

Presence of candidiasis

Respiratory system

Presence of signs of focal versus multilobar pneumonia

Cardiovascular system

Murmurs, prosthetic heart sounds

Abdominal examination

Signs of peritonitis

Hepatomegaly or splenomegaly

Tenderness of renal allograft

Neurologic examination

Nuchal rigidity

Cranial nerve signs

NONINVASIVE LABORATORY TESTS

White blood cell count and differential

Blood and urine cultures

Serum cryptococcal antigen

Serum galactomannan antigen (aspergillosis)

Serum and urine *Histoplasma* antigen

Urinary *Legionella* antigen

INVASIVE LABORATORY TESTS

Bronchoalveolar lavage

Pleural fluid aspiration

Upper gastrointestinal endoscopy

Colonoscopy

Biopsy of liver, kidney, bone marrow

CMV, cytomegalovirus; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; HSV, herpes simplex virus.

infection. In solid organ transplant recipients, specific causes of pulmonary infection are most frequent at certain times post transplantation (Table 127-5). In a similar manner, specific causes of pulmonary infection are more frequent at different CD4 lymphocyte counts for patients with HIV infection (Table 127-6).

A normal chest radiograph does not rule out pulmonary infection in immunocompromised patients. Additionally, although some diseases have suggestive radiologic findings (e.g., apical cavitations in tuberculosis), most radiographic findings have to be interpreted in light of all other data available. Frequently, computed tomography

TABLE 127-4

Host Defenses Against Respiratory Infections and How They Are Affected in Immunocompromised Patients

| LOCATION | HOST DEFENSE | DEFECT |
|----------------------------|--|--|
| Upper airway | Filtration Mucociliary apparatus Cough | Endotracheal intubation CF, cigarette smoking Impaired consciousness |
| Lower airway (nonspecific) | Alveolar macrophages Polymorphonuclear leukocytes | Immunosuppressive medication, corticosteroids Corticosteroids, malnutrition, chemotherapy, malignancies |
| Lower airway (specific) | B lymphocytes T lymphocytes | Hypogammaglobulinemia, CLL, MM AIDS, malignancies, immunosuppressants |

AIDS, acquired immunodeficiency syndrome; CF, cystic fibrosis; CLL, chronic lymphocytic leukemia; MM, multiple myeloma.

TABLE 127-5

Occurrence of Pulmonary Infection After Solid Organ Transplantation Stratified by Time from Transplantation

| TIME AFTER TRANSPLANT (MO) | ORGANISM |
|----------------------------|--|
| <1 | Nosocomial bacteria (e.g., MRSA, ESBL-producing Enterobacteriaceae, <i>Pseudomonas aeruginosa</i> , <i>Acinetobacter baumannii</i>) <i>Legionella</i> spp. Respiratory viruses (e.g., influenza virus, parainfluenza virus, RSV, adenovirus, rhinovirus, human metapneumovirus) <i>Aspergillus</i> spp. |
| 1-6 | Nosocomial bacteria (if still mechanically ventilated) <i>Legionella</i> spp. <i>Nocardia</i> spp. [†] <i>Mycobacterium tuberculosis</i> Herpesviruses (e.g., HSV, VZV, CMV) [‡] Respiratory viruses (e.g., influenza virus, parainfluenza virus, RSV, adenovirus, rhinovirus, human metapneumovirus) <i>Pneumocystis jirovecii</i> [†] <i>Cryptococcus neoformans</i> <i>Aspergillus</i> spp. <i>Coccidioides</i> spp. <i>Histoplasma</i> spp. |
| >6 | Bacteria associated with community-acquired pneumonia (e.g., <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Legionella</i> spp., <i>Mycoplasma pneumoniae</i>) <i>Nocardia</i> spp. [†] <i>Rhodococcus equi</i> [*] <i>Mycobacterium tuberculosis</i> Atypical mycobacterium <i>Aspergillus</i> spp. [*] <i>Zygomycetes</i> [*] <i>Cryptococcus neoformans</i> [*] |

*These organisms should be considered when immune-suppression is still substantial.

†These organisms are less likely in patients on prophylactic cotrimoxazole.

‡These viruses are less likely in patients on prophylactic ganciclovir or valganciclovir.

CMV, cytomegalovirus; ESBL, extended-spectrum β -lactamase; HSV, herpes simplex virus; MRSA, methicillin-resistant *Staphylococcus aureus*; RSV, respiratory syncytial virus; VZV, varicella-zoster virus.

TABLE 127-6

Etiology of Pulmonary Infections in Patients Infected with Human Immunodeficiency Virus, Stratified by CD4 Lymphocyte Count

| ORGANISM | CD4 COUNT (CELLS/mm ³) | | | |
|---------------------------------|------------------------------------|------------------------|-----------------------------------|----------------------------------|
| | >500 | 200-500 | 50-200 | <50 |
| <i>Streptococcus pneumoniae</i> | | <i>S. pneumoniae</i> | <i>Pneumocystis jirovecii</i> | <i>P. jirovecii</i> |
| <i>Haemophilus influenzae</i> | | <i>H. influenzae</i> | <i>Mycobacterium tuberculosis</i> | <i>Cryptococcus</i> |
| | | <i>M. tuberculosis</i> | <i>Cryptococcus</i> | CMV MAC <i>Aspergillus</i> |

CMV, cytomegalovirus; MAC, *Mycobacterium avium* complex.

(CT) is required (e.g., evaluation of pulmonary nodules). Pulmonary nodules have a broad differential diagnosis in immunocompromised patients, including infections due to fungi (especially *Cryptococcus neoformans*, *Coccidioides immitis*, and *Aspergillus fumigatus*), *Nocardia*, mycobacteria, *Rhodococcus equi*, and *Bartonella*. Additionally, carcinomas and posttransplant lymphoproliferative disorders may present with pulmonary nodules. The differential diagnosis of cavitary lesions includes mycobacteria, invasive pulmonary aspergillosis, legionellosis, and infection with *R. equi*. As noted earlier, the broad differential diagnosis of pulmonary infection in immunocompromised patients mandates early and aggressive diagnostic strategies such as bronchoscopy with the bronchoalveolar lavage sent for a comprehensive battery of microbiological investigations.

Central Nervous System Infections

Most infectious agents reach the CNS via hematogenous dissemination from an extraneural site. Exceptions include retrograde propagation of infected thrombi within emissary veins, spread along olfactory nerves, and spread from a contiguous focus of infection. The blood-brain barrier presents a natural and an efficient barrier to hematogenous infection. The function of the blood-brain barrier in immunocompromised patients has not been well studied. It is well known, however, that when a CNS infection is established, immune defenses (even in immunologically competent hosts) are inadequate to control the infection. Local opsonization is deficient within the brain. In animal models of bacterial brain abscess, corticosteroid administration led to a reduction in macrophage and glial response, with an increased number of viable bacteria in the abscess.²⁵

Bacterial meningitis due to *N. meningitidis* is relatively uncommon in immunocompromised patients, except if they have undergone splenectomy. In contrast, pneumococcal meningitis seems to occur with increased frequency in patients who have undergone stem cell transplantation²⁶⁻²⁸ and in those with HIV infection.^{29,30} Meningitis due to *Listeria monocytogenes* is classically associated with immunocompromise, reflecting the need for adequate T-cell function and IFN- γ production to kill this intercellular pathogen.³¹ In addition to meningitis, *Listeria* infection may be associated with a brain abscess, particularly that occurring in the brainstem.^{32,33} Enteric bacteria (e.g., *Escherichia coli*) are rare causes of bacterial meningitis in immunocompromised patients. A classic association exists, however, between meningitis with such organisms and disseminated infection with *Strongyloides stercoralis*.^{34,35} In the presence of immunosuppression (e.g., large doses of corticosteroids), *Strongyloides* can migrate from the gastrointestinal (GI) tract to the CNS, carrying enteric bacterial flora into the CNS. Mortality is high without prompt recognition and treatment. *Nocardia* and mycobacteria must also be considered in the differential diagnosis of CNS infections in immunocompromised patients;

TABLE 127-7

Central Nervous System Infections in the Immunocompromised Host

| ETIOLOGIC AGENT | SPECIAL CONSIDERATIONS |
|-----------------------------------|---|
| MENINGITIS | |
| <i>Streptococcus pneumoniae</i> | Especially in HIV-infected individuals |
| <i>Listeria monocytogenes</i> | Predilection for brainstem |
| Enteric bacteria | Associated with disseminated <i>Strongyloides</i> infection |
| <i>Cryptococcus neoformans</i> | Rapid diagnosis by cryptococcal antigen or India ink stain |
| <i>Mycobacterium tuberculosis</i> | Consider PCR for rapid diagnosis |
| MENINGOENCEPHALITIS | |
| HSV | Rare in immunocompromised patients |
| HHV-6 | May be associated with lack of CSF pleocytosis |
| VZV | Skin lesions yield diagnosis |
| West Nile virus | Transmitted via transplanted organ or blood |
| SPACE-OCCUPYING LESIONS | |
| <i>Nocardia</i> | Pulmonary lesions usually also present |
| <i>Toxoplasma gondii</i> | Especially in HIV-infected individuals |
| Fungi | Pulmonary lesions usually also present |

CSF, cerebrospinal fluid; HHV-6, human herpesvirus-6; HIV, human immunodeficiency virus; HSV, herpes simplex virus; PCR, polymerase chain reaction; VZV, varicella-zoster virus.

diagnostic samples should be sent for inoculation onto appropriate media for isolation of these organisms.³⁶⁻³⁸

Fungal infection of the CNS may cause meningitis or space-occupying lesions. Cryptococcal meningitis is associated with advanced HIV infection (CD4 lymphocyte count <100/mm³) but can also occur in transplanted patients.³⁹ The presentation is usually subacute, although dangerous elevations in intracranial pressure are sometimes observed. Space-occupying lesions in the brain may occur with disseminated mold infections; these infections usually arise in the lung, but dissemination to the brain is part of multiorgan spread. Mortality is extremely high in these cases. Any of the pathogenic molds^{40,41} such as *Aspergillus*,² zygomycetes,^{42,43} *Scedosporium*,⁴⁴ or *Fusarium*⁴⁵ can undergo dissemination to the brain. The dimorphic fungi (e.g., *Histoplasma*, *Coccidioides*) may also disseminate from the lung, causing infection of the CNS. Zygomycetes may also be associated with frequently fatal infection arising within the nose or sinuses (rhinocerebral mucormycosis).^{42,43}

The most common protozoal pathogen to affect the CNS is *Toxoplasma gondii*. The classic association is between *T. gondii* infection and advanced HIV infection, although cases have shown associations with other forms of immunocompromise.⁴⁶⁻⁴⁸ Amebic encephalitis has been reported occasionally in conjunction with advanced HIV infection or organ transplantation.⁴⁹

Additionally, a variety of viruses can cause CNS infections in immunocompromised patients. Perhaps as a result of the widespread use of antihherpesvirus prophylaxis in many immunocompromised populations, herpes simplex virus (HSV) encephalitis is rare.⁵⁰ Some of the newer herpesviruses, such as HHV-6, have been associated with neurologic infection in transplant recipients.⁵¹⁻⁵³ Lack of diagnostic capabilities for these viruses may partially explain their apparent infrequency. CMV meningoencephalitis is well described in patients with advanced HIV infection⁵⁴ and occasionally has been reported in transplant recipients.⁵⁵ Further, disseminated infections with varicella-zoster virus (VZV) in immunocompromised patients may result in CNS infection; West Nile virus may also be acquired from transplanted organs or blood transfusions and is associated with a significant meningoencephalitis in transplant recipients.^{56,57} Table 127-7 summarizes the agents capable of causing CNS infections in an immunocompromised host.

The wide variety of organisms that could be responsible for CNS infection presents a need for a broadly based diagnostic workup before empiric therapy is begun. If the cerebrospinal fluid (CSF) is collected, it should be sent for Gram stain and Ziehl-Neelsen stain for rapid diagnosis of bacterial and mycobacterial infections. PCR can be performed for the diagnosis of most viral infections such as HSV, CMV, and VZV. Cryptococcal antigens can be detected rapidly in the CSF, enabling a rapid diagnosis of this form of meningitis, but for patients with space-occupying lesions of the brain, collection of the CSF may not be possible. Aspiration may be performed in some circumstances. Before invasive diagnostic testing of the brain is performed, however, the patient's skin is examined for lesions (such as that which may occur with cryptococcosis or nocardiosis), and the lungs are carefully reviewed by CT. Because most CNS lesions arise from infection in other parts of the body, a diagnosis may often be made more easily by microbiological sampling of these body sites.

Gastrointestinal Infections

Severe GI infections in immunocompromised patients may occasionally warrant ICU admission because of dehydration or visceral perforation. As with respiratory and CNS infections, the differential diagnosis is usually broad, and a precise diagnosis rarely can be made based on clinical suspicion alone. Immunocompromised patients have an increased predisposition to GI infections, depending on the type and degree of immunocompromise and exposure to certain pathogens.

The most commonly involved organisms in the etiology of infective esophagitis or gastritis are *Candida*, CMV, and HSV, although a variety of other organisms (e.g., mycobacteria and zygomycetes) occasionally are implicated. Candidal esophagitis is a common opportunistic infection in patients with AIDS. Approximately 13.3 events of candidal esophagitis per 100 person-years occur in HIV-infected patients with CD4 counts less than 300/mm³.⁵⁸ A study of renal transplant patients in the United States showed that esophageal candidiasis is the most common fungal infection in these patients, making up 22% of all fungal infections.⁵⁹ Other predisposing factors for severe esophageal candidiasis include broad-spectrum antibiotic therapy, steroid therapy, cancer chemotherapy, diabetes mellitus, cutaneous burns, radiotherapy, and hematologic stem cell transplant. Although *C. albicans* is the most frequently diagnosed organism, there is an increase of other species, including *C. krusei* and *C. glabrata*—this is notable because of the increase in resistance to fluconazole in these species. Finally, as noted previously, immunocompromised patients may have a combination of pathogens causing infection at any one time. Upper GI endoscopy with biopsy is the gold standard for making the diagnosis.

Diarrhea is a common problem in immunocompromised patients with multifactorial etiologies. It may lead to the diagnosis of immunosuppression in a previously undiagnosed patient when an opportunistic pathogen is found and appropriately investigated. Severe complications such as malabsorption leading to malnutrition, dehydration, and wasting can occur. Occasionally, intestinal perforation may result from a GI infection. In an immunosuppressed patient, it is important to differentiate diarrhea due to opportunistic infections from diarrhea due to neoplasms, GVHD, drugs, and other therapeutic agents. GVHD accounts for more diarrhea in blood and bone marrow transplant patients than infective organisms.⁶⁰ In these patients, organisms that cause mild self-limiting disease in the normal host may cause severe and life-threatening infections.⁶⁰

Prolonged use of multiple antibiotics in high doses predisposes patients to colonization with *Clostridium difficile* and development of pseudomembranous colitis. Antibiotic prophylaxis to prevent *P. jirovecii* pneumonia or spontaneous bacterial peritonitis has been associated with *C. difficile*. In addition to the classic antibiotic risk factors of clindamycin or cephalosporin use, fluoroquinolones may predispose to epidemic strains of *C. difficile* (BI/NAP1/027 strain).⁶¹ Enteric bacterial pathogens such as *Salmonella* occur at increased frequency in immunocompromised patients, especially HIV-infected individuals. In

some regions of Africa, nontyphoidal *Salmonella* infections are among the most common causes of bacteremia.⁶² Severe *Salmonella* infections may be associated with intestinal perforation. *Shigella*, *Campylobacter jejuni*, *E. coli* (enterotoxigenic, enteroadherent, and enteroaggregative), and *Yersinia* species are other bacterial causes of diarrhea, although they are less commonly associated with bacteremia.

Protozoal infections are seen more commonly in HIV-infected patients than other immunocompromised groups. At CD4 counts less than 200 cells/mm³, patients with HIV infection may present with unusual protozoa (e.g., *Cryptosporidium* and *Microsporidium*). Occasionally, these pathogens are also seen in transplant recipients.^{63,64} Such pathogens are not detected on routine microscopic examination for ova, cysts, and parasites. Special stains and microbiological techniques are needed. A routine examination usually detects *Giardia lamblia*, *Entamoeba histolytica*, and other more common pathogenic protozoa.

CMV can cause significant colitis in all immunocompromised populations. CMV colitis may occur in the absence of systemic evidence of infection (i.e., PCR finding on peripheral blood may be negative^{65,66}). An intestinal biopsy may be required to make the diagnosis. A CMV intestinal infection may present with diarrhea but may have more profound presentations such as intestinal perforation.^{67,68}

Finally, mycobacterial infections such as tuberculosis occasionally can be associated with colitis.⁶⁹ *M. avium* complex can be grown readily from the feces of patients with HIV infection and CD4 counts less than 50/mm³, but it is not always the cause of diarrhea in such patients.

THERAPEUTIC DIFFICULTIES IN IMMUNOCOMPROMISED PATIENTS

Empiric Therapy

The choice of empiric antimicrobial therapy is often difficult in immunocompromised patients because of the broad differential diagnosis involved and the substantial risk of antimicrobial resistance (stemming from prolonged hospitalization and frequent prior use of antibiotics). As emphasized earlier, management of infection in an immunocompromised patient can be simplified by narrowing the differential diagnosis by thorough history taking, review of prior medical records, and careful physical examination. Aggressive early diagnostic maneuvers before beginning empiric antimicrobial therapy can enable a definitive diagnosis to be made. Failure to collect specimens before beginning empiric therapy can lead to prolonged, expensive, and unnecessary therapy.

Empiric antibiotic therapy in suspected bacterial infections should be tailored to the individual to maximize the chance that the therapy is microbiologically adequate. There is a clear link between microbiologically adequate empiric therapy and successful outcomes from infections in the ICU.⁷⁰ In settings such as severe pneumonia in an immunocompromised patient, empiric regimens comprising vancomycin, ciprofloxacin, meropenem, amphotericin (or voriconazole), ganciclovir, and trimethoprim/sulfamethoxazole may be necessary to cover potentially lethal infections with methicillin-resistant *Staphylococcus aureus*, *P. aeruginosa*, *Legionella*, fungi, CMV, and *P. jirovecii*. However, increasing resistance to carbapenems may necessitate consideration of newer antibiotics such as ceftazidime-avibactam and ceftolozane-tazobactam. Nephrotoxic antibiotics such as colistin, polymyxin B, or amikacin may be problematic in immunocompromised patients with baseline renal impairment, despite the activity of these antibiotics against many carbapenem-resistant organisms.

There is no established role of combination empiric therapy with antifungal agents. The decision to start empiric mycobacterial therapy is never an easy one. In general, it is only advised when there is a substantial risk of tuberculosis. Empiric therapy for disseminated *Strongyloides* infection may have a role in immunocompromised patients coming from an endemic area and with the classic presentation of disseminated infection.

Immunocompromised patients presenting with acute meningitis should receive treatment that covers *S. pneumoniae* and *L. monocytogenes*. The combination of vancomycin, ampicillin, and ceftriaxone may be necessary (vancomycin and ceftriaxone for multidrug-resistant *S. pneumoniae* and ampicillin for *Listeria*). The combination of amphotericin and 5-flucytosine is recommended empirically for meningitis in which antigen testing or India ink stain of the CSF reveals encapsulated fungi consistent with *C. neoformans*. Immunocompromised patients with space-occupying lesions of the brain can be treated empirically with an antifungal drug (amphotericin or voriconazole) if the suspicion of disseminated fungal infection is high, although nocardiosis, toxoplasmosis, or mycobacterial infection would not be covered without specific therapy.

For immunocompromised patients with severe diarrhea requiring ICU admission, empiric therapy with metronidazole or oral vancomycin (for *C. difficile*) and ganciclovir (for CMV) may be given after fecal samples have been collected. Colonic biopsy may be necessary if it can be safely performed. For immunocompromised patients with intestinal perforation, antibiotic coverage against gut flora (i.e., treatment of peritonitis) plus treatment of the most likely causes of perforation (e.g., ganciclovir for CMV) may be chosen.

Pathogen-Directed Therapy

The importance of appropriate specimen collection is that empiric therapy can be streamlined (de-escalated) if cultures or other diagnostic tests reveal positive findings. With immunocompromised patients, antimicrobial therapy is often complicated by drug interactions or adverse reactions. Transplant recipients taking calcineurin inhibitors (e.g., cyclosporine or tacrolimus) or HIV-infected patients taking protease inhibitors are most at risk because these drugs may be metabolized by the cytochrome P450 system.^{71,72} Significant interactions may occur between rifampin, macrolide antibiotics, azole antifungal drugs, and calcineurin inhibitors.⁷² Aggressive treatment of infections in immunocompromised hosts (e.g., with amphotericin, pentamidine, or foscarnet) may be associated with renal dysfunction, compounding the nephrotoxic effects of calcineurin inhibitors. Antimicrobial agents such as linezolid or ganciclovir frequently cause neutropenia, potentially adding further host defense defects.

CONCLUSION

Infection is likely to be one of the most significant problems an immunocompromised patient faces. These patients may present with severe infection or acquire infection while critically ill due to other causes. Prevention of infection in the ICU is of primary importance. Pneumonia can be readily prevented by many strategies. Ventilator-associated pneumonia may be prevented by a bundle of interventions.⁷³ Aspiration of subglottic secretions and selective digestive tract decontamination, while supported by some trials, are still controversial. Opportunistic pneumonia with *P. jirovecii* can be prevented by use of prophylaxis with trimethoprim/sulfamethoxazole, dapsone, or nebulized pentamidine. Environmental exposure to *Legionella* and *Aspergillus* spp. can be prevented by ensuring water purification techniques (e.g., copper-silver ionization) and by preventing exposure of patients

to construction activity. Infections due to pathogens transmitted human to human, such as *M. tuberculosis*, can be prevented by isolation precautions.

Many extrapulmonary infections can also be prevented. CMV infection can be prevented by universal prophylaxis with ganciclovir, valganciclovir, valacyclovir, or a preemptive approach using serial PCR of peripheral blood.^{74,75} A similar preemptive approach may be useful in preventing aspergillosis by monitoring peripheral blood for the galactomannan antigen, although this remains controversial.^{76,77} *C. difficile* infection is difficult to prevent because there is a clear need for antibiotic therapy for immunocompromised patients with infection. The increasing incidence, severity, and high rate of recurrence of *C. difficile* infection have become significant problems.⁷⁸ A recent randomized controlled study demonstrated that the addition of monoclonal antibodies against *C. difficile* toxins to antibiotic agents significantly reduced the recurrence of *C. difficile* infection, even among patients with the epidemic BI/NAP1/027 strain.⁷⁹ Finally, attention to classic infection control practices such as appropriate immunizations,⁸⁰⁻⁸² hand hygiene, and contact isolation is paramount in immunocompromised patients.

Acknowledgment

The contributions of Dr. Yoshiro Hayashi to a previous edition of this book are gratefully acknowledged.

KEY POINTS

1. The degree of immunocompromise in a patient is a guide to the likelihood of particular opportunistic infections and may be indicated by the type and timing of immunosuppressive therapy and, in human immunodeficiency virus-infected patients, by the CD4 lymphocyte count and viral load.
2. Environmental exposures can be important predictors of infection type. Travel history and exposure to *Mycobacterium tuberculosis*, *Aspergillus*, or *Legionella* are important considerations.
3. The differential diagnosis of opportunistic lung infection in immunocompromised hosts is so broad that bronchoscopy with bronchoalveolar lavage, before antimicrobial therapy, is highly desirable.
4. Central nervous system lesions in immunocompromised hosts are often the result of disseminated infection. Careful examination of the skin, with biopsy of suspicious lesions, and computed tomography of the lungs may obviate the need for brain biopsy.
5. Antimicrobial therapy in immunocompromised hosts is beset by difficulties with antimicrobial resistance (especially carbapenem resistance), drug interactions, and adverse effects. Increased frequency of monitoring of immunosuppressive drug levels is essential.

ANNOTATED REFERENCES

Fishman JA. Infection in solid-organ transplant recipients. *N Engl J Med* 2007;357:2601–2614.

This review article is suitable to comprehensively understand management of infections associated with solid organ transplantation. It describes clinical problems related to the use of solid organ transplants, potential drug interactions with medications commonly used in the ICU, and controversies surrounding the use of antiretroviral therapy in the ICU.

Huang L, Quartin A, Jones D, Havlir DV. Intensive care of patients with HIV infection. *N Engl J Med* 2006;355:173–181.

Antiretroviral therapy has changed the long-term prognosis and clinical spectrum of diseases in patients with HIV infection who are admitted to the ICU.

Keane J, Gershon S, Wise RP, et al. Tuberculosis associated with infliximab, a tumor necrosis factor- α neutralizing agent. *N Engl J Med* 2001;345:1098–1104.

Although patients with rheumatoid arthritis may become immunocompromised by way of therapy with corticosteroids or methotrexate, the development of anticytokine agents for this condition has

opened the way for a new range of opportunistic infections in this patient population. This study showed that tuberculosis occurs with increased frequency in patients receiving infliximab.

Kotton CN, Kumar D, Caliendo AM, et al. International consensus guidelines on the management of CMV in solid organ transplantation. *Transplantation* 2010;89:779–795.

CMV is one of the most common infections after solid organ transplantation, resulting in significant morbidity and mortality. However, management of CMV varies considerably among transplant centers. This evidence and expert opinion-based guidelines include topics on diagnostics, immunology, prevention, treatment, resistance, and pediatrics.

Kowalski R, Post D, Schneider MC, et al. Immune cell function testing: an adjunct to therapeutic drug monitoring in transplant patient management. *Clin Transplant* 2003;17:77–88.

The degree of immunocompromise and the subsequent risk of infection in transplant recipients have been difficult to quantify. This study examined the utility of an in vitro immune cell function assay as a means of quantifying global immune response in transplant recipients.

Infectious endocarditis (IE) is a rare disease with an incidence of 3 to 10 episodes per 100,000 person-years, varying among countries and increasing dramatically with age. It is presently classified by the mode of acquisition (e.g., healthcare-associated IE, community acquired, and IE in intravenous drug users [IVDU]), by localization as left- or right-sided prosthetic or native valve IE, or as cardiac implantable electronic device (CIED) related (e.g., pacemaker or cardioverter defibrillator). The new classification of *healthcare-associated infectious endocarditis* (HAIE) includes patients hospitalized for more than 48 hours before the symptoms of IE develop (previously called *nosocomial IE* [NIE]) or patients with symptoms less than 48 hours after admission but with extensive healthcare contact defined as (1) home-based nursing or IV therapy, hemodialysis, or IV chemotherapy fewer than 30 days before onset of IE symptoms; (2) hospitalization fewer than 90 days before onset of IE; or (3) residency in a nursing home or a long-term care facility. The definition of HAIE applies both to native (NVE) and prosthetic valve endocarditis (PVE). Early prosthetic valve endocarditis (now defined as presenting <1 year post surgery) has a portion included in the HAIE definition.^{1,2}

HAIE was estimated to have occurred in 0.8 of 10,000 hospital admissions and is often diagnosed late during hospitalization (39 ± 25 days).³ It is associated with considerable morbidity and mortality. The current in-hospital mortality rate for patients with IE is 15% to 20%, with a 1-year mortality approaching 40%.⁴

HEALTHCARE-ASSOCIATED NATIVE VALVE ENDOCARDITIS

The current understanding of HAIE has been based primarily on retrospective studies with a small sample size. New data emerged from the International Collaboration on Endocarditis Prospective Cohort Study (ICE-PCS) from 61 medical centers in 28 countries.⁵ From this database, as defined by the modified Duke criteria, native valve IE in patients without IV drug abuse was recognized in 1622 patients. Of these patients, 1065 had a community-acquired infection, and 557 (34%) had healthcare-associated native valve endocarditis (HANVE), consistent with the contemporary high incidence of healthcare-associated infection.⁶ Almost half of these infections were acquired outside of the hospital, a result consistent with previous reports of healthcare-associated bacteremia. Compared with patients with community-acquired IE, patients with HANVE more often have comorbid conditions (e.g., diabetes mellitus, cancer, or long-term immunosuppressive therapy). Fever is the most common presenting feature, but physical signs of IE present more rarely in HANVE, suggesting a more acute course. Nonnosocomial acquisition of HANVE is most often dependent on hemodialysis or an intravascular catheter (54%), while patients with nosocomial acquisition more often have a preexisting valvular disease or undergo a nondental invasive medical procedure. The mitral valve is most frequently involved, followed by the tricuspid and aortic valve.⁵ Staphylococci (both *Staphylococcus aureus* and coagulase-negative strains) represent the major pathogens in HAIE. *S. aureus* is responsible for 52% to 57% of HAIE episodes, 91% of which have an intravascular device as the most probable source of bacteremia.³ In the ICE-PCS study, *S. aureus* was the most common pathogen in HANVE, among which 47% was methicillin-resistant *S. aureus* (MRSA).⁵ The second most common bacteria was enterococci (15%), followed by coagulase-negative strains of staphylococci (13%).

MRSA is more prevalent in hospital-acquired infections (57% vs. 41% of HANVE acquired outside the hospital).⁵ Among coagulase-negative strains of staphylococci, *Staphylococcus lugdunensis* deserves attention because it behaves like *S. aureus* with high virulence, has a 50% probability of complicated infection when isolated in blood, and an aggressive course when it is the cause of IE.⁷

Gram-negative bacilli are rare causes of HANVE despite the fact that they cause lethal bacteremias in hospitals, probably as a result of their decreased ability to adhere to heart valves and susceptibility to bactericidal action of serum.^{3,8} Recently, cases of IE due to MDR and XDR gram-negatives (e.g., *Pseudomonas*, *Acinetobacter*, and *B. cepacia*) have been published with poor outcomes despite aggressive management because of a lack of effective treatment options.

Fungal infectious endocarditis is a rare infection, comprising in total less than 2% of IE cases, with a mortality rate exceeding 30%. However, an increased frequency of fungal endocarditis has been observed in recent years, attributed to the increasing use of vascular lines, as well as to noncardiac surgery and increased numbers of immunocompromised patients.^{9,10} The fungi most commonly associated with endocarditis are *Candida* (*albicans* and non-*albicans*, 50%-80%) and *Aspergillus* spp. (20%-25%). In contradistinction to *Candida* spp., in which blood cultures in cases of IE are positive in 83% to 95% of cases, blood cultures are positive in only 11% or less of patients with *Aspergillus* spp. In cases of fungal endocarditis, prolonged symptoms before hospitalization and the embolization of major arteries are classic findings. However, the diagnosis is delayed or missed in 82% of patients. For fungal endocarditis to be diagnosed early, it should be considered in the differential diagnosis and echocardiography performed, which then demonstrates large, bulky vegetations. Peripheral blood cultures should be obtained and accessible embolic specimens subjected to histologic examination.^{9,10} HANVE has higher mortality compared to community-acquired NVIE (25% versus 13%). In HANVE, factors recognized to be independently associated with increased risk of death are increased age (>60), diabetes, *S. aureus* infection, paravalvular abscess, stroke, heart failure, and new conduction abnormality. Cardiac surgery during the IE episode is found to be associated with a lower mortality,⁵ and therefore, early surgical intervention is often mandatory. In fungal endocarditis, the removal of the infected valve is indicated, and postsurgery suppressive therapy for 2 or more years along with close follow-up is required to detect relapses.^{9,10} Special consideration should be given to chronic hemodialysis (HD) patients, in whom IE is significantly more common (16-18 times) and causes greater morbidity and mortality. In this group of patients, IE is the second leading cause of death after cardiovascular disease, and it has been proposed to be added as a fifth category in classification by acquisition.^{11,12} In the ICE-PCS study, 63% of HANVE were HD patients.⁵ *S. aureus* was the pathogen in 75% to 80% of cases, half of which were MRSA. Fever may not be present, and blood cultures may less often be positive, complicating a diagnosis by the Duke criteria. Mortality remains high: 30% during the first month, about 65% during the first year, and reaching more than 70% if cardiac surgery is indicated. An age older than 65, diabetes as the cause of renal failure, mitral involvement, large vegetations, septic emboli, and infections due to MRSA or VRE have been identified as risk factors for mortality.¹¹

For methicillin-sensitive *S. aureus* (MSSA), antistaphylococcal penicillins should be the treatment of choice whereas, in cases of

MRSA with minimum inhibitory concentration (MIC) over 1 mg/L to vancomycin, antimicrobial choices include daptomycin and linezolid.¹ If vancomycin is indicated, drug levels should be followed, with trough levels of 25 to 30 mg/L required for efficacy.¹³

HEALTHCARE-ASSOCIATED PROSTHETIC VALVE ENDOCARDITIS

PVE accounts for 9.5% to 20% of all cases of IE, with mortality rates ranging between 25% and 60%.¹⁴ It occurs in 3% to 4% of patients within 5 years after surgery.

More than one-third is health-care acquired. Contamination of prosthetic valves during this early period occurs either directly at the time of implantation by a break in sterile surgical techniques or via transient episodes of bacteremia, emanating mostly from infected intravascular catheters and wound or skin infections while the patient is still hospitalized, therefore representing a real nosocomial infection.¹⁴ Early PVE (<1 year) presents mostly during the first 2 to 3 months after surgery.

PVE may manifest as an indolent illness with low-grade fever and immune-mediated manifestations or as a fulminant acute febrile disease with hypotension. When early PVE is caused by *S. aureus*, the clinical picture is accompanied in more than 40% of cases by the central nervous system (CNS) and intracardiac complications, with a subsequent mortality ranging from 42% to 85%. The microbiology of PVE is shown in Table 128-1. In the ICE-PCS study, 556 definite cases of PVE were found among 2670 cases of IE (20%), with 36.5% being healthcare-associated prosthetic valve endocarditis (HAPVE) and 70% acquired in the hospital.¹⁴ Of the cases of PVE, 71% were diagnosed during the first year post surgery and the majority on day 60 (median on day 84). In 43% of HAPVE, an intravascular device was in place. *S. aureus* was the most common pathogen E, with a higher incidence in cases with HAPVE (34% and 13.3% MRSA), followed by coagulase-negative staphylococci.¹⁴

Recent progress in transesophageal echocardiography (TEE), applying a high-resolution biplane or multiplane transducer, has enhanced the diagnostic approach to PVE. Sensitivity and specificity of TEE in the diagnosis of PVE exceeds 90% versus a sensitivity of 40% to 70% with transthoracic echocardiography (TTE).¹⁵ New diagnostic modalities are currently used and recommended for the diagnosis of PVE, including multislice cardiac CT, 18F-FDG PET/CT and radiolabeled leukocyte SPECT/CT, when suspicion for the presence of PVE is high and the TEE is not diagnostic. These new methods have been incorporated in the modified Duke criteria (Table 128-2) in the last

update of guidelines of IE, which are effectively used to confirm the diagnosis of PVE.^{15,16} Mortality in PVE is still substantial, being higher in early PVE (77%) than in late-onset infection (42%). The leading causes of death in early PVE are septic shock (36%), congestive heart failure (29%), and renal failure (21%).^{3,17,18} In the ICE-PCS study, overall mortality for PVE was 22.8%, with the mortality from HAPVE being higher at 30.5%. Other factors related to an increased risk of death were older age, *S. aureus* as the pathogen, and complications such as heart failure, stroke, intracardiac abscess, and persistent bacteremia.¹⁶ The survival rate with medical therapy alone in cases of moderate to severe chronic cardiac failure due to prosthesis dysfunction is almost nil. However, valve replacement in this group plus antimicrobial therapy will achieve a survival rate of 44% to 64%.¹⁹ It is noteworthy that PVE recurs in only 6% to 15% of patients who are operated on with active bacterial invasive infection. After surgery for the removal of the infected prosthetic valve, antibiotics should be continued for at least 6 weeks.¹⁴

INFECTIVE ENDOCARDITIS IN THE ICU

Five studies have focused on patients with IE admitted to the ICU in the past decade.²⁰⁻²⁴ Patients with IE are admitted because of complications (e.g., severe sepsis or septic shock, heart failure with hemodynamic instability, embolic phenomena especially from the CNS, multiorgan failure, or after acute surgery for IE). They usually need prolonged hospitalization, and more than 50% undergo cardiac surgery, which is a protective factor for mortality. A total of 15% to 20% of IE patients admitted to the ICU are healthcare associated, 15% to 36% involve a prosthetic valve, and one-third are accompanied by embolic phenomena most commonly from the CNS. Pathogens recorded are usually *Staphylococcus aureus* and streptococci. Mortality rates are 30% to 45%, among studies, for the first 30 days, with risk factors for mortality in recent years being high values of severity scores at admission (SAPS II, SOFA) and multiorgan failure. Long-term mortality has been recently studied by Mirabel et al.,²⁴ and it was found to be 69% for the subsequent 5 years, with risk factors for mortality being a high SOFA score at admission, the presence of a prosthetic valve, and the size of the vegetation (>15 mm). IE may also be acquired in the ICU, usually as a result of bacteremia related to a medical procedure, and *S. aureus* is the most common pathogen.²⁵ The expected classic clinical features of IE are often not present in ICU patients. For instance, central nervous system (CNS) signs due to sedation may be blunted, and manifestations of renal failure are usually attributed to septic multiple organ dysfunction syndrome.

TABLE 128-1 Etiology of Prosthetic Valve Endocarditis Versus Nosocomial Native Valve Endocarditis

| | NATIVE VALVE ENDOCARDITIS | | PROSTHETIC VALVE ENDOCARDITIS | |
|--|---------------------------|--------------------|-------------------------------|---------------|
| | HEALTHCARE ASSOCIATED | COMMUNITY ACQUIRED | EARLY (<12 mo) | LATE (>12 mo) |
| <i>Streptococcus</i> species | 8% | 28% | 3.8% | 20% |
| <i>Enterococcus</i> species | 15% | 9% | 7.5% | 12.7% |
| <i>Staphylococcus aureus</i> | 45% | 20% | 36% | 18% |
| MRSA | 47% | 12% | 19% | 3.3% |
| Coagulase-negative <i>Staphylococcus</i> | 13% | 6% | 17% | 19.9% |
| Gram-negative bacilli* | | | 3% | 1.2% |
| HACEK* | | | 0% | 2.1% |
| Fungi* | | | 9.4% | 3.3% |
| Culture negative | 5% | 11% | 11.2% | 12.4% |

Modified from Benito N, Miró JM, de Lazzari E, et al. Health care-associated native valve endocarditis: importance of non-nosocomial acquisition. *Ann Intern Med* 2009;150:586-94; and from Wolff M, Witzsch S, Chastang C, et al. Prosthetic valve endocarditis in the ICU: prognostic factors of overall survival in a series of 122 cases and consequences for treatment decision. *Chest* 1995;108:688-94.

*Rare; approximately 2% among all cases of native valve endocarditis.

HACEK, *Haemophilus* spp. (*H. parainfluenzae*, *H. aphrophilus*, *H. paraphrophilus*), *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, *Kingella* spp.; MRSA, methicillin-resistant *Staphylococcus aureus*.

TABLE 128-2 Modified Duke Criteria for the Clinical Diagnosis of Infectious Endocarditis**MAJOR CRITERIA****1. BLOOD CULTURES POSITIVE FOR IE**

- a. Typical microorganisms consistent with IE from two separate blood cultures:
 - *Viridans* streptococci, *Streptococcus gallolyticus* (*Streptococcus bovis*), HACEK group, *Staphylococcus aureus*; or
 - Community-acquired enterococci, in the absence of a primary focus; or
- b. Microorganisms consistent with IE from persistently positive blood cultures:
 - ≥ 2 positive blood cultures of blood samples drawn >12 h apart; or
 - All of 3 or a majority of ≥ 4 separate cultures of blood (with and last samples drawn ≥ 1 h apart); or
- c. Single positive blood culture for *Coxiella burnetii* or phase I IgG antibody titer $>1:800$

2. IMAGING POSITIVE FOR IE

- a. Echocardiogram positive for IE:
 - Vegetation;
 - Abscess, pseudoaneurysm, intracardiac;
 - Valvular perforation or aneurysm;
 - New partial dehiscence of prosthetic valve.
- b. Abnormal activity around the site of prosthetic valve implantation detected by 18F-FDG PET/CT (only if the prosthesis was implanted for >3 months) or radiolabeled leukocytes SPECT/CT.
- c. Definite paravalvular lesions by cardiac CT.

MINOR CRITERIA

1. Predisposition such as predisposing heart condition or injection drug use.
2. Fever as temperature $>38^{\circ}\text{C}$.
3. Vascular phenomena (including those detected by imaging only): major arterial emboli, septic pulmonary infarcts, infectious (mycotic) aneurysm, intracranial hemorrhage, conjunctival hemorrhages, and Janeway's lesions.
4. Immunologic phenomena: glomerulonephritis, Osler's nodes, Roth's spots, and rheumatoid factor.
5. Microbiological evidence: positive blood culture but does not meet a major criterion as noted above or serological evidence of active infection with an organism consistent with IE.

DEFINITE IE

- Two major criteria; or
- One major criterion and three minor criteria; or
- Five minor criteria

POSSIBLE IE

- One major criterion and one minor criterion; or
- Three minor criteria

REJECTED IE

- Firm alternate diagnosis; or
- Resolution of symptoms suggesting IE with antibiotic therapy for ≤ 4 days; or
- No pathologic evidence of IE at surgery or autopsy, with antibiotic therapy for ≤ 4 days; or
- Does not meet criteria for possible IE, as above

From Task Force for the Management of Infective Endocarditis of the European Society of Cardiology (ESC): 2015 ESC Guidelines for the management of infective endocarditis. Eur Heart J 2015;36(44):3075-128.

Since the risk of HAIE is proportionally increased with the duration of hospitalization, the diagnosis of IE should always be suspected in the presence of a fever of unknown origin with positive blood cultures after a prolonged stay in the ICU. The latter suspicion is strengthened in patients with prosthetic valves or cardiac implantable electronic devices (CIED), in those undergoing procedures that may damage the right side of the heart, and whenever bacteremia lasts for more than 72 hours after catheter removal and/or positive blood cultures that persist 3 days after starting appropriate antimicrobials, especially if the microorganism isolated in blood is *S. aureus*.²⁶

The diagnostic value of echocardiography in the diagnosis of IE and particularly of the transesophageal view has been established. In a patient with *S. aureus* bacteremia, a TTE should always be performed. If bacteremia persists beyond 48 to 72 hours and/or the patient has an implantable cardiac device or a prosthetic valve, then a TEE should also be performed because the risk of IE is high.^{27,28} In the case of a negative TEE, if clinical suspicion continues to be high, a second examination should be advocated (a multislice CT for native valves and 18F-FDG PET/CT, as well as radiolabeled leukocyte SPECT/CT for prosthetic valves or CIED).¹ HAIE in the ICU requires the prompt initiation of antimicrobial therapy and cardiosurgical evaluation, keeping in mind that mortality increases sharply with *S. aureus* as a pathogen, with age, and with the origin of the infection (i.e., ICU-acquired vs. community-acquired). Of note, the treatment duration of catheter-related staphylococcal (*S. aureus*) bacteremia aiming to treat successfully any seeded valve (as occurs in 23% of the cases) should never be shorter than 2 weeks, and echocardiography should be performed before treatment discontinuation. Otherwise, a treatment duration of 4 weeks is recommended.²⁹

Prophylaxis of HAIE, especially in ICU patients, mandates (1) IV access and intravascular procedures to be performed with aseptic care; (2) IV and intraarterial catheters to remain in place for as brief a duration as possible; and (3) tunnelization, although a controversial issue, to be considered either as an immediate approach for temporary dialysis catheters or as a systemic procedure if the catheter has been or will be in place for more than 4 days.³⁰ Antimicrobial prophylaxis is not justified before performing TEE.¹

KEY POINTS

1. ICU infectious endocarditis (ICU-IE) shares overlapping characteristics with healthcare-associated infectious endocarditis (HAIE) and is either acquired in the ICU or is an emergency necessitating critical care, involving native or prosthetic valves.
2. Major pathogens (90%) include staphylococci (*S. aureus*, with increasing rates of MRSA) and *Enterococcus* spp.
3. Mortality of HAIE is higher in the elderly, in patients with *S. aureus* and fungal endocarditis, and in patients with complications (e.g., heart failure, stroke, intracardiac abscess, persistent bacteremia). Early surgical intervention is mandatory and may improve the in-hospital outcome.
4. Fungal endocarditis is rare, presenting as a complication of intravascular instrumentation or surgery or in the context of an immunocompromised state. *Candida* is the most common fungal causative agent. Delayed diagnosis, major embolic phenomena, and large vegetations are the rule. Combined surgical and medical treatment of long duration is needed to ameliorate the high ($>50\%$) mortality rate.
5. Transesophageal echocardiography (TEE) has enhanced our diagnostic approach in HAIE (NVE or PVE), especially when the Duke diagnostic clinical criteria are effectively used, and it must always be performed in patients with persisting *S. aureus* bacteremia and prosthetic valves or CIED.

Medical advances continue to improve the prognosis of patients with cancer and other immunodeficiencies. In the past 50 years, the field of transplantation has greatly impacted the management of patients with cancer and renal, cardiac, and liver diseases. Moreover, advances in neonatology continue to increase the survival of premature infants. These advances have benefited society greatly, but they have also fueled the emergence of invasive fungal infections. *Candida* species first appeared as significant nosocomial pathogens approximately 30 years ago.¹ For two decades, infections caused by these pathogens increased dramatically.

Fungal infections among critically ill patients are primarily due to *Candida* spp. However, infections caused by other opportunistic fungal pathogens including *Aspergillus*, *Fusarium*, Mucorales, and *Cryptococcus neoformans* also occur in critically ill populations (e.g., solid-organ transplant [SOT] and hematopoietic stem cell transplant [HSCT] recipients and patients with acquired immunodeficiency syndrome [AIDS]). Moreover, primary or endemic mycosis caused by *Blastomyces dermatitidis*, *Coccidioides immitis*, and *Histoplasma capsulatum* can cause severe disseminated infection in immunocompetent or compromised hosts.

Fungal infections are generally more prevalent in intensive care units (ICUs) than on the general medical wards.² The importance of effective preventive measures against invasive fungal infection is widely appreciated in patients with leukemia or in HSCT recipients. As our understanding of these infections continues to improve, so too does the ability to institute appropriate preventive measures. In the past decade, the development of agents possessing either different modes or a broader spectrum of activity, less toxicity, or a reduced propensity to interact with other drugs has increased the number of systematically active antifungal agents available. Consequently, clinicians can now tailor antifungal therapy to specific patients. Moreover, our understanding of antifungal pharmacodynamics is developing, and methods to measure susceptibility to antifungal agents are improving.

FUNGAL INFECTIONS IN THE CRITICALLY ILL

Candida Infections in the ICU

Epidemiology

Candida albicans remains the fourth most common pathogen in healthcare-associated infections; only coagulase-negative staphylococci, *Staphylococcus aureus*, and enterococci are more common.³ *Candida* spp. have consistently caused a substantial disease burden for at least the past decade.⁴⁻⁶ ICUs have a higher incidence of *Candida* bloodstream infections (BSIs) than medical and surgical wards.^{2,7} Although prior data had suggested the frequency of *Candida* BSIs among ICU patients had declined, estimates from national secondary databases and population-based studies suggest the disease burden may be shifting from the ICU to the general hospital population.¹

C. albicans remains the most common invasive *Candida* spp. worldwide.⁸ However, decreasing trends in the isolation of these species over time have been observed in the ICU and non-ICU setting.^{8,9} An increased prevalence of *C. albicans* and *C. parapsilosis* among neonatal ICU patients and an increasing prevalence of *C. glabrata* infections

among adults has been widely appreciated.^{1,8-11} *C. albicans* is responsible for approximately 45% of episodes of candidemia.¹² The incidence of infection due to a particular *Candida* sp. varies considerably by the clinical service on which the patient is hospitalized. However, in general, *C. albicans* is the primary fungal pathogen in the ICU setting, followed by *C. glabrata*, *C. parapsilosis*, *C. tropicalis*, *C. krusei*, *C. guilliermondii*, and *C. lusitaniae*.¹² This rank order varies little across infection site, but it may vary with age, underlying disease, or local epidemiology.^{1,8,9,12} Surveillance data have noted that candidemia in neonatal ICUs is predominantly due to *C. albicans* and *C. parapsilosis* and rarely to *C. glabrata* or other *Candida* spp.^{1,8,9,12} Surveillance studies have demonstrated that BSI due to *C. albicans* occurs less frequently with increasing age.^{1,8,9,12} In contrast, *C. glabrata* is rarely isolated among infants and children but is more frequently found with increasing patient age.^{1,8,9,12}

C. albicans is part of the normal flora of the gastrointestinal tract. Infections including BSIs caused by most *Candida* spp., particularly *C. albicans*, arise endogenously from the gastrointestinal mucosa, skin, and urinary tract.¹³ Invasive *Candida* infections occur when alteration of endogenous flora leads to overgrowth of yeast which, in the presence of compromised skin or gastrointestinal mucosa integrity, translocates from its commensal environment to the bloodstream.¹³ However, *Candida* spp., including *C. albicans*, may be transmitted exogenously in ICU settings.^{14,15} Exogenous transmission of non-*albicans* *Candida* spp. through indirect contact with the ICU environment occurs commonly.¹⁴ For example, *C. parapsilosis* is an exogenous pathogen known for its ability to form biofilms on catheters and inert devices. *C. parapsilosis* persists in the nosocomial environment.¹⁶ Moreover, it is spread throughout the hospital through hand carriage by healthcare workers.¹⁶ Therefore, colonization with this pathogen is not a prerequisite for infection.¹⁶

Mortality

Candida BSIs are often difficult to detect. Symptomatically, BSIs due to *Candida* spp. are indistinguishable from BSIs of bacterial etiology. *Candida* spp. are cleared from the blood very efficiently by several organs, particularly the liver, and blood cultures yield positive results in only 50% of patients with hematogenously disseminated candidiasis.^{17,18} However, the ability of automated blood culture systems to recover *Candida* spp. has continued to improve. For example, in a simulated candidemia study, *Candida* spp. were isolated in 74% (479/648) of blood culture bottles.¹⁹ However, isolation rates were highest in aerobic blood and mycology culture bottles (98% [211/216] and 97% [210/216], respectively) but lowest in anaerobic culture bottles (27% [58/216]).¹⁹ The ability to detect growth improved as inoculum size increased.¹⁹ Although the time to detect growth varied with *Candida* spp., most species were detected within 24 to 48 hours. Growth was detected faster in aerobic and mycology culture bottles than in anaerobic bottles. These data and other studies demonstrated the improved ability of current technology to detect simulated or clinical candidemia due to most common and uncommon *Candida* pathogens in aerobic cultures.^{19,20} New nanomolecular diagnostic approaches with T2 magnetic resonance were developed to enable timely diagnosis, and these show promising results.²¹

Even with improved ability to recover *Candida* spp. from the blood, *Candida* BSIs carry a relatively poor prognosis. *Candida* spp. isolated

from the blood have consistently been identified as an independent predictor of mortality.²²⁻²⁴ The overall attributable mortality of nosocomial BSIs among critically ill patients is 35%.²⁵ This mortality rate for nosocomial BSIs in the ICU setting is comparable to the mortality rate associated with BSIs due to *Candida* spp. Historically, the estimated crude mortality rate associated with *Candida* BSIs hospital-wide and in the ICU setting has ranged from 35% to 69%, while the estimated attributable mortality has been 38%.^{24,26,27}

Recent estimates suggest that the mortality attributable to candidemia and other forms of invasive candidiasis ranges from 10% to approximately 50%.¹ Moreover, data demonstrate that despite the advent of potent and safer antifungal therapy, the mortality risk associated with candidemia has essentially remained unchanged for at least two decades.^{28,29} Inadequate treatment may be a reason why mortality has not improved despite the availability of potent and safe antifungal therapy. Delays in administration, treatment with an agent to which the organism is resistant, inadequate dosing or treatment duration, or failure to recognize and treat candidemia all contribute to the mortality associated with *Candida* BSI.³⁰⁻³⁶ Delaying initiation of adequate antifungal therapy even 12 to 48 hours is independently associated with mortality in patients with candidemia.^{31,32,34,37-39}

Candidemia produces significant morbidity and increases the length of hospital stay.^{1,13} Given the severity of illness associated with this infection, the added length of stay utilizes significant healthcare resources.⁴⁻⁶

Risk Factors

Among critically ill patients, risk factors for *Candida* infections are well described.^{7,40-44} Broad-spectrum antimicrobial use, colonization, indwelling vascular catheters, extremes of age, and hemodialysis have been consistently identified as independent risk factors for *Candida* BSIs.^{7,24} In most ICU settings, many of these risk factors are commonly present and unavoidable. The ICU itself provides an ideal environment for transmission of *Candida* spp. among patients; thus it is not surprising that prolonged ICU stay has been identified as an independent risk factor.⁴⁵ A study using validated risk factors in a simulated ICU population demonstrated that in the presence of multiple risk factors, the probability of infection increases exponentially.⁴⁵ For example, in a hypothetical critical care unit, if a patient had prior exposure to four antibiotic classes, the calculated risk of candidemia for that patient would range from 5% to 35%, depending on the overall baseline candidemia rate in the ICU, usually between 1% and 5%. However, if that same hypothetical patient subsequently had *Candida* spp. cultured from another (nonbloodstream) anatomic site, the calculated risk would increase substantially to 40% to 80%.⁴⁵ Given how common many of the risk factors (such as indwelling catheters, antibiotics, immunosuppressants, and total parenteral nutrition) are in the ICU, these data illustrate the need to accurately predict or identify patients who truly are at risk so that therapy can be instituted as early as possible.

The risk factors for BSIs with any *Candida* spp. are similar, and the specific type of infection cannot be differentiated based on clinical characteristics alone.^{40,41} Several studies have developed prediction rules to stratify patients at increased risk for developing invasive infections with either *C. albicans* or other *Candida* spp. in hopes of providing guidance for clinical decision making to prevent candidemia in the ICU. These prediction rules are based upon retrospective studies and assess the combination of ICU length of stay, prior *Candida* colonization, and other host risks.⁴⁶⁻⁴⁸ While these systems demonstrate risk stratification is possible, they are somewhat complicated to apply, and some have questioned the practicality of certain components of individual prediction rules.^{41,49} Using the database from a large prospective multicenter Spanish study in which fungal colonization was assessed weekly along with other potential risk factors, León and colleagues developed the “*Candida* score” based upon four independent risk factors: multifocal *Candida* spp. colonization, surgery upon ICU admission, severe sepsis, and total parenteral nutrition. The score, obtained by adding the statistical weight of each risk factor, has a cutoff

value of 2.5, providing a sensitivity of 81% and specificity of 74% for identifying patients with current or future *Candida* infection. Patients with a score greater than 2.5 were more than 7 times as likely to have proven infection as patients with a *Candida* score ≤ 2.5 .⁴⁷ A prospective multicenter observational study demonstrated that a *Candida* score ≥ 3 discriminated between colonization and invasive candidiasis in nonneutropenic ICU patients colonized with *Candida* spp., with a minimum length of ICU stay of 7 days.⁴⁹ These data lend credence to the idea of using the *Candida* score for guiding the start of empiric antifungal therapy in the ICU. However, even though the *Candida* score is promising, the clinical utility of such prediction rules in establishing the benefit of targeted antifungal prophylaxis remains to be established in prospective studies.⁵⁰⁻⁵²

Opportunistic Fungal Infections in Immunocompromised Critically Ill Patients

Invasive Aspergillosis in Critically Ill Patients with Hematologic Malignancies

In contrast to *Candida* spp., the burden of infection due to *Aspergillus* spp. is small.^{1,13} *Aspergillus* spp. cause infection in critically ill populations immunocompromised by burns, cytotoxic chemotherapy, prolonged corticosteroid therapy, malignancy, leukemia, SOT or HSCT, and other congenital or acquired immunodeficiencies. *Aspergillus* spp. are ubiquitous environmental molds. While several hundred species of *Aspergillus* have been described, relatively few are known to cause disease in humans. Most *Aspergillus* infections are acquired exogenously via inhalation. In the absence of an effective immune response, airborne conidia invade sinus or lung vasculature. Although the lung is the most common site of invasive aspergillosis, *Aspergillus* spp. also demonstrate tropism for cutaneous, central nervous system (CNS), bone, and cardiac vasculature.⁵³

The incidence of invasive aspergillosis in immunocompromised patients varies among specific populations. Among patients with hematologic malignancies, those with acute myelogenous leukemia have the highest incidence of invasive aspergillosis.⁵⁴⁻⁵⁶ Patients in ICUs are at increased risk and susceptibility in general, depending on the use of immunosuppressants, structural lung damage and genetic predisposition.⁵⁷⁻⁶³ Like patients with leukemia, patients undergoing HSCT are at high risk for invasive aspergillosis. The incidence of invasive aspergillosis varies depending on transplant type but not the type of conditioning regimen (myeloablative vs. nonmyeloablative). The incidence is higher among allogeneic HSCT recipients than among recipients of autologous stem cells. In the HSCT population, whether the incidence of invasive aspergillosis is truly increasing or decreasing is difficult to ascertain, because the rate of autopsies continues to decline. The incidence of invasive aspergillosis among SOT is highest after lung transplant and lowest after renal transplant. Patients receiving HSCT or SOT can develop invasive aspergillosis shortly (within 40 days) after transplantation, but typically it occurs late post-HSCT (>40-100 days) or SOT (>90 days).⁶⁴⁻⁶⁹

In patients with acute leukemia or in HSCT recipients, prolonged neutropenia after cytotoxic chemotherapy or HSCT is the primary risk for early invasive aspergillosis. Risk factors associated with invasive aspergillosis in HSCT and SOT recipients vary with time after the transplant. However, in general, risks early in the transplant process are related to transplant-related factors (underlying disease, neutropenia, type of transplant), biological factors (hyperglycemia, iron overload), and extrinsic factors (spores from the environment, air filtration). In contrast, risks for invasive aspergillosis occurring later in the transplant process include transplant complications such as acute GVHD (grade ≥ 3) and high-dose corticosteroid therapy.⁶⁸

Lesions associated with invasive pulmonary aspergillosis evolve over a period of weeks. CT findings, especially nodular infiltrates with a “halo sign,” are strongly suggestive of invasive aspergillosis or infection from other angioinvasive fungi in immunocompromised patients. Moreover, this finding is associated with significantly improved

response and survival if antifungal therapy is initiated shortly upon detection of this sign of infection.⁷⁰

Recent diagnostic efforts have focused on detecting non-culture-based serum markers (e.g., galactomannan test, 1,3- β -D-glucan, polymerase chain reaction). Galactomannan is a cell wall constituent of *Aspergillus* spp. that can be detected in the serum during invasive infection. The test is specific for invasive aspergillosis and is commercially available as a sandwich enzyme immunoassay that detects circulating galactomannan. The values from this test have been shown to correlate strongly with the clinical outcome of patients with invasive aspergillosis.⁷¹⁻⁷³ Because 1,3- β -D-glucan is a cell-wall component of many fungal pathogens, it can be detected by colorimetric detection assays. Although the test is highly sensitive, the presence of 1,3- β -D-glucan in the serum is not specific for any fungi. Using both of these non-culture-based serum markers may improve the ability to diagnose invasive aspergillosis in high-risk populations and could lead to earlier diagnosis or improved monitoring of the success of antifungal therapy.^{74,75} CT-guided biopsy has a high diagnostic yield, and samples should undergo both histopathologic and cultural evaluation.⁷⁶ The combination of radiologic, serologic, cultural, histopathologic, and clinical data may ultimately improve the diagnosis of invasive aspergillosis and speed up initiation of appropriate antifungal therapy.

Miscellaneous Pathogens in Critically Ill Patients with Hematologic Malignancies

Candida and *Aspergillus* spp. are the primary fungal pathogens in critically ill patients with hematologic malignancies. However, other pathogens such as *Fusarium* spp., *Pseudallescheria* spp./*Scedosporium apiospermum*, and the members of the Mucorales order are increasing in frequency.¹³ Each of these less common organisms has particular clinical characteristics or tissue tropism. In addition, they are often less susceptible than *Aspergillus* spp. to systemic antifungal agents. Consequently, infections due to these pathogens are associated with high mortality. Of these, the Mucorales are the most common among critically ill patients. These angioinvasive pathogens are acquired through inhalation and produce a necrotic infection with the highest morbidity and mortality.⁷⁷ Rhinocerebral, paranasal, pulmonary, cutaneous and gastrointestinal infections are common manifestations of mucormycosis. Common risks are diabetic ketoacidosis, immunosuppression, organ transplantation, (traumatic) skin damage, and a prolonged ICU stay.^{77,78} Pulmonary and disseminated infections mostly affect patients with hematologic malignancy, while rhinocerebral and paranasal mucormycosis is predominant in patients with uncontrolled diabetes.^{79,80} The “reversed halo” sign on CT is indicative of pulmonary mucormycosis, although the diagnosis should be confirmed by cultural and histopathologic evaluation of biopsy specimens.⁸¹⁻⁸³ Management of mucormycosis, including the important role of surgical débridement, is detailed in a current guideline of the European Confederation of Medical Mycology.⁸⁴

Cryptococcosis, Histoplasmosis, Blastomycosis, and Coccidioidomycosis in Critically Ill Patients

Cryptococcus neoformans, *C. deneoformans*, *Histoplasma capsulatum* var. *capsulatum*, *Blastomyces dermatitidis*, and *Coccidioides immitis* are not common pathogens in the ICU setting. These organisms can cause infection in patients with intact immune function. However, with the exception of *B. dermatitidis*, severe infections due to these pathogens are more common among critically ill immunocompromised populations, particularly those with AIDS and recipients of SOT. Cryptococcosis is the third most common invasive fungal infection among SOT recipients.^{13,85}

C. neoformans is a ubiquitous encapsulated yeast isolated from diverse environmental sources (e.g., soil, trees and plant material, and pigeon droppings). This pathogen is primarily acquired by inhalation.⁸⁶ In the lung, the organism elicits a cell-mediated response involving neutrophils, monocytes, and macrophages. The cryptococcal

polysaccharide capsule, an important virulence factor, facilitates laboratory identification and recognition by host cell-mediated immune response, and it possesses immunosuppressive properties. The advent of AIDS significantly altered the incidence of cryptococcosis. Before the AIDS epidemic, cryptococcosis was an uncommon disease in the United States, but since then, the majority of cases have been associated with HIV infection.^{87,88} The prevalence of cryptococcosis in HIV in the United States has declined with the widespread use of fluconazole and highly active antiretroviral therapy to treat HIV infection. Cryptococcosis still produces significant acute mortality, but overall long-term outcomes have improved dramatically in the past two decades.⁸⁹ Mortality among HIV-infected patients and SOT recipients is similar and is estimated to be approximately 15% to 20%.⁸⁹⁻⁹¹

Among critically ill immunosuppressed populations, cryptococcal infections typically involve the CNS.⁸⁵ However, HIV-negative patients may have only extra-CNS (i.e., skin, soft tissue, or osteoarticular) manifestations. The onset of this infection may be acute or gradual, and patients often present with nonspecific complaints.⁹² When the disease manifests as subacute meningitis or meningoencephalitis, classic meningeal findings such as photophobia or nuchal rigidity may be absent.

In cases of cryptococcal meningitis, characteristic cerebrospinal fluid (CSF) findings may be present; however, CSF leukocyte count can be low, and CSF protein and glucose values may be normal. Therefore, CSF analysis for cryptococcal antigen and culture of the organism are required to diagnose cryptococcal meningitis. Detection of the organism by India ink stain is highly specific but has low sensitivity. Determination of serum cryptococcal antigen using latex agglutination is a highly sensitive and specific test and is therefore an important component of the diagnosis of cryptococcal disease. In patients with cryptococcal meningitis, particularly those with AIDS, the serum cryptococcal antigen is usually positive, and titers are commonly very high. Detection of antigen in the CSF strongly suggests infection, but in HIV-infected patients, false-negative results can occur in up to 10%, even in the presence of positive cultures. The definitive diagnosis of cryptococcal infection requires a positive culture for *C. neoformans*.

Histoplasmosis (caused by *H. capsulatum* var. *capsulatum*), blastomycosis (*B. dermatitidis*), and coccidioidomycosis (*C. immitis*) are the major endemic mycoses found in North America. Infections by these pathogens occur primarily in distinct geographic areas, but owing to population mobility, they can be reported throughout the United States. Diagnosis is established via antigen and antibody detection from urine or serum, respectively.^{93,94} *H. capsulatum* is endemically distributed primarily in the Mississippi and Ohio River valleys. *B. dermatitidis* is found chiefly in the south central United States, the Mississippi and Ohio River valleys, and in certain regions of Illinois and Wisconsin. *C. immitis* is found mainly in the arid southwest regions of the United States. Infection with all these pathogens is acquired via inhalation. Overall, hospitalization is required in an estimated 4.6 and 28.7 cases per million children and adults, respectively.⁹⁵ Nationwide, endemic mycoses require substantial healthcare resources to manage, and they produce significant crude mortality rates in children and adults (5% and 7%, respectively).⁹⁵ The severity of histoplasmosis depends on host immune function and the extent of exposure, particularly in the immunocompetent host. Hematogenous dissemination from the lungs occurs in all infected patients, but in immunocompetent hosts, it is controlled by the reticular endothelial system. However, among elderly hosts or those with cell-mediated immune disorders (e.g., HIV infection), progressive dissemination of the infection readily occurs. After inhalation, *B. dermatitidis* can disseminate from the lungs to other organs as the yeast form. The primary pneumonia is often undetected and resolves without sequelae. Endogenous reactivation in the lungs, skin, or bones is often the first sign of infection.

C. immitis requires the inhalation of only a few arthroconidia to produce primary coccidioidomycosis. Like the other endemic mycoses, in the majority of patients, it typically manifests as an asymptomatic pulmonary disease.⁹⁶ However, it can also manifest

as an acute respiratory illness, chronic progressive pneumonia, pulmonary nodules and cavities, extrapulmonary nonmeningeal disease, and meningitis.^{97,98}

Among critically ill patients, histoplasmosis manifests as either chronic pulmonary histoplasmosis or progressive disseminated (extrapulmonary) histoplasmosis. Chronic or cavitary pulmonary histoplasmosis occurs in middle-aged and elderly patients with underlying lung disease that compromises the ability of nonspecific host defenses to effectively clear the organism.

Progressive disseminated histoplasmosis occurs in healthy or critically ill immunocompromised hosts, but it is more common and severe in the latter population (e.g., patients with malignancies or HIV infection). The infection can disseminate to a variety of organs including the reticuloendothelial system, oropharyngeal and gastrointestinal mucosa, skin, adrenal glands, and kidneys.⁹⁶

Clinical manifestations of blastomycosis can mimic many other diseases, such as tuberculosis and cancer, but it typically occurs as an asymptomatic infection, acute or chronic pneumonia, or disseminated (extrapulmonary) disease.⁹⁹ Extrapulmonary blastomycosis typically afflicts the skin, bones, and genitourinary system.⁹⁹ Cutaneous lesions are the most common skin manifestations of this disease.⁹⁹ Extrapulmonary (disseminated) coccidioidomycosis afflicts 1% to 5% of all patients infected with *C. immitis* and is deadly if not treated properly. Even with appropriate treatment chronic infection is common.⁹⁷

■ SYSTEMIC ANTIFUNGAL AGENTS

Amphotericin B Formulations

Amphotericin B Deoxycholate

Amphotericin B deoxycholate (AmB-d), a polyene antifungal agent, disrupts biological membranes, thereby increasing their permeability. AmB-d also stimulates the release of cytokines that cause arteriolar vasoconstriction in the renal vasculature.¹⁰⁰

Pharmacology and Pharmacokinetics. The majority (70%) of an administered AmB-d dose is recovered from the urine and feces over a 7-day period; approximately 30% of the administered dose remains in the body a week after dosing.¹⁰¹

Overview of Toxicity. AmB-d infusion-related reactions, including hypotension, fever, rigors, and chills, occur in approximately 70% of patients.¹⁰²⁻¹⁰⁶ These reactions occur early in therapy and often subside with time. Pretreatment regimens consisting of diphenhydramine, acetaminophen, meperidine, and hydrocortisone may be used to prevent infusion-related reactions. The efficacy of these regimens is unclear, so their routine use is discouraged until the reactions occur, after which pretreatment regimens should be employed with subsequent dosing.¹⁰² Although common and noxious, infusion-related reactions rarely cause early termination of AmB-d therapy or interfere with the use of other medications.

AmB-d also produces dose-related toxicities, including nephrotoxicity, azotemia, renal tubular acidosis, electrolyte imbalance, cardiac arrhythmias, and anemia,^{100,103} of which AmB-d-induced nephrotoxicity is the most common.¹⁰⁷ In the ICU, this toxicity often limits the use of AmB-d or interferes with the ability to use other medicines. Saline hydration before dosing can reduce the incidence of AmB-d-induced nephrotoxicity, but in the ICU setting, the utility of saline hydration may be limited by fluid restriction necessary to manage the fluid status of critically ill patients. Use of the deoxycholate formulation of amphotericin B is discouraged in most, if not all, indications.¹⁰⁸

Lipid Amphotericin B Formulations

Amphotericin B lipid complex (ABLC) and liposomal amphotericin B (LAmB) are lipid amphotericin B formulations that in many centers have supplanted the use of AmB-d. They retain the activity of AmB-d but have significantly less associated nephrotoxicity than the parent drug.^{107,109}

Pharmacokinetic Comparisons of Lipid Amphotericin B Formulations. The lipid amphotericin B formulations differ in physicochemical properties and composition. These differences produce subtle differences in their pharmacokinetic behavior that may ultimately prove to be clinically significant. The disposition and activity of these formulations in human tissue is poorly characterized. However, animal data indicate that high serum concentrations may influence the delivery of lipid AmB formulations to certain infection sites such as the CNS and lungs.¹¹⁰

Toxicity Comparisons of Lipid Amphotericin B Formulations. Compared with AmB-d, the lipid formulations have significantly less associated nephrotoxicity.¹⁰⁷ The formulations differ in the incidence of infusion-related reactions and other adverse events associated with AmB-d infusion.^{105,111} These reactions typically do not result in early termination of therapy.^{111,112} Observational safety comparisons between ABLC and LAmB suggest the two formulations have a similar nephrotoxicity profile, but prospective comparative data suggest LAmB is less nephrotoxic than ABLC.^{107,113,114} There are few data comparing the safety of lipid AmB formulations to the azole antifungal agents in critically ill patients.

Azole Antifungal Agents

Fluconazole, Itraconazole, Isavuconazole, Posaconazole, and Voriconazole

The systemic azoles exert a fungistatic effect by dose-dependent inhibition of cytochrome P450 (CYP)-dependent 14 α -demethylase. This enzyme is necessary for the conversion of lanosterol to ergosterol, leading to the depletion of ergosterol, the essential sterol of the fungal cell wall, an event that ultimately compromises cell wall integrity. The degree of inhibition varies among the different azole agents, which accounts for differences in the spectrum of activity.

Pharmacology and Pharmacokinetics. The azoles differ in chemical properties, forming the basis of the pharmacokinetic differences between the agents and the propensity of this class to interact with other medications.

Several studies have examined fluconazole pharmacokinetics in critically ill patients.¹¹⁵⁻¹¹⁷ In surgical ICU patients, fluconazole clearance correlates with creatinine clearance (CrCl), and its volume of distribution correlates with body weight.¹¹⁶ In addition, fluconazole's volume of distribution is greater in this population than in healthy volunteers.¹¹⁶ The fluconazole half-life is markedly prolonged in surgical ICU patients.¹¹⁶ In patients with severe renal dysfunction (CrCl < 30 mL/min), some authors recommend dosage reductions of 50%,¹¹⁶ but such reductions should be made cautiously and take into account the infecting pathogen in patients receiving fluconazole via enteral feeding tubes.¹¹⁶ Data suggest that the systemic availability of fluconazole is relatively unaffected by administration by feeding tube. However, serum concentrations obtained with standard doses administered in this way may not be adequate to treat certain infections such as those caused by *C. glabrata*.¹¹⁷ Moreover, in critically ill patients with abdominal trauma with and without abdominal wall closure, intravenous (IV) fluconazole may be warranted because the bioavailability of enterally dosed fluconazole in these patients is highly variable.¹¹⁵

Itraconazole is a highly lipophilic weak base and practically insoluble in water. It is available as a capsule and as an oral solution formulated in hydroxypropyl- β -cyclodextrin (HP- β CD). The IV solution was removed from the U.S. market in 2008; however, this dosage form may be available in other countries. Slow and erratic absorption of the capsule formulation precludes its use in critically ill ICU patients. HP- β CD enhances itraconazole solubility and improves its oral systemic availability. HP- β CD itself is poorly absorbed from the gastrointestinal tract, stimulates gastrointestinal secretion and propulsion, and causes diarrhea.

Under fasting conditions in healthy adults, itraconazole is rapidly absorbed when given as an oral solution, and compared with the capsule form, there is less interpatient and inpatient variability in serum concentrations.¹¹⁸ After IV administration, renal elimination of

itraconazole is negligible, but HP- β CD is renally eliminated (80%-90%). IV itraconazole is therefore contraindicated in cases of significant renal impairment ($\text{CrCl} \leq 30 \text{ mL/min}$) because of concerns over accumulation of HP- β CD. Rare cases of congestive heart failure are documented in the literature.¹¹⁹

Isavuconazole is available as an IV formulation and capsules since March 2015.¹²⁰ It has a prolonged half-life of 100-130 hours, with persisting tissue levels enabling once daily dosing after a 1-day loading dose. Oral absorption is independent of food intake.¹²¹⁻¹²³ Isavuconazole clearance is dependent on hepatic CYP3A4 metabolism. Based on data from animal studies, it is hypothesized that it is excreted in the feces.¹²⁴

Posaconazole is available in oral suspension, delayed-release tablet, and IV formulations. It exhibits linear pharmacokinetics with doses between 50 and 800 mg/d. However, absorption of the oral suspension is saturated at doses exceeding 800 mg/d. Posaconazole oral suspension absorption is influenced by gastric pH and is optimal under acidic conditions. Both absorption and exposure are maximized by dividing the total daily dose and giving it 4 times daily rather than administering it as a single dose.^{125,126} Posaconazole absorption and exposure are also enhanced by administration with or shortly after a meal, although in the ICU, it is often impractical to give it that way. However, absorption and exposure are also enhanced by administering the drug with a liquid nutritional supplement. With the introduction of the posaconazole tablet formulation, the issue of pH- and meal-dependent absorption is overcome.¹²⁷ In critically ill patients—for example, those with severe mucositis or on mechanical ventilation—IV administration is preferred.¹²⁸ Although posaconazole binds extensively (>95%) to plasma proteins, its large estimated volume of distribution suggests that it distributes widely throughout the body. There are, however, few data describing its penetration into the CSF. Posaconazole is primarily eliminated in feces and urine as unchanged drug.

Voriconazole is a derivative of fluconazole with limited aqueous solubility and improved antifungal activity. It is available in IV and oral formulations. IV voriconazole contains sulfobutyl ether β -cyclodextrin (SBECD) as a solubilizing agent. There are few data on how critically ill patients handle voriconazole. In healthy volunteers, voriconazole exhibits good oral availability and wide tissue distribution, with hepatic metabolism and renal excretion of metabolites.¹²⁹ In patients with moderate to severe renal impairment, SBECD accumulates, and it is recommended that oral dosing be used in patients with a CrCl less than 50 mL/min.¹³⁰ Oral dosing in critically ill patients is often not possible, however. Therefore the question of how SBECD is handled in critically ill patients on dialysis has been examined. A small study observed accumulation of SBECD in three patients during hemodialysis. No toxicity due to this accumulation was observed, and the accumulated dose values were lower but comparable with those used in previous toxicity studies with animals.¹³⁰ Nonetheless, if possible, use of IV voriconazole in patients on hemodialysis should be avoided. Data demonstrate that voriconazole achieves adequate CSF concentrations.^{129,131}

For all azoles, therapeutic drug monitoring is generally indicated as pharmacokinetic variability is extensive and levels may be unpredictable.¹³²

Overview of Toxicity. The azoles are a relatively safe class of drugs and are associated with few serious adverse effects. The advent of fluconazole and subsequent agents greatly improved the safety of this class. All the azoles are associated with gastrointestinal intolerance, transient transaminitis, hepatic toxicity, rashes, and dizziness. Nausea, vomiting, and diarrhea commonly occur with all agents in this class, particularly with oral itraconazole solution. These effects are usually observed with high doses of the azoles, but rarely are they severe enough to warrant discontinuation of therapy. All azoles may produce significant elevations in transaminases. Patients experiencing azole-associated transaminase abnormalities are asymptomatic, but these increases can on rare occasions evolve into fatal drug-induced hepatitis. The azoles can also produce allergic skin rashes that are generally mild and subside with discontinuation of the drug.

Fluconazole is perhaps the safest azole, and doses four to five times the recommended daily dose have been well tolerated. Reported adverse effects of isavuconazole are gastrointestinal disturbances, transaminase abnormalities, and hypersensitivity reactions.¹²³ Whether isavuconazole leads to QTc prolongation or shortening is not yet understood.^{123,133,134} The common adverse effects associated with posaconazole have been similar to those observed with the other agents in the class (i.e., gastrointestinal, transient transaminase abnormalities), but it appears to be more tolerable than earlier azoles.¹³⁵ During phase II and III clinical trials, QTc prolongation was described in 4% of patients.¹³⁶ In addition to the adverse effects seen with other azoles, voriconazole produces transient visual disturbances in approximately 30% of patients, which rarely lead to discontinuation of therapy. These disturbances are acute and include changes in color discrimination, blurred vision, photophobia, and the appearance of bright spots.

Azole Drug Interactions. Drug interactions occur primarily in the intestine, liver, and kidneys by a variety of mechanisms. In the intestine, they can occur as a result of changes in pH, complex formation with ions, or interference with transport and enzymatic processes involved in gut wall (i.e., presystemic) drug metabolism. In the liver, drug interactions can occur because of interference with drug-metabolizing enzymes. Drug interactions in the kidney can occur through interference with glomerular filtration, active tubular excretion, or by other mechanisms. The azoles are one of the few drug classes that can cause or be involved in drug interactions at all of these anatomic sites by one or more of the above mechanisms. Drug interactions involving the azoles have been extensively reviewed.¹³⁷ Several of the drug-drug interactions involving the azoles occur class-wide. Therefore, when using the azoles, the clinician must be aware of the many drug-drug interactions, both real and potential, associated with this class.

Interactions involving the azoles result because of their physicochemical properties. All azoles are somewhat lipophilic and thus undergo CYP-mediated metabolism.¹³⁸ The azoles all inhibit one or more CYP enzymes. Of the five azoles reviewed here, itraconazole and isavuconazole interact significantly with P-glycoprotein (P-gp), which is a transport protein involved in drug distribution.^{124,137} Fluconazole is not affected by agents that increase gastric pH, but its potential to cause CYP-mediated interactions is more than that suggested by in vitro studies. CYP-mediated interactions involving fluconazole are often dose dependent and can involve drugs metabolized by CYP3A4 (e.g., midazolam, rifampin, phenytoin) and CYP2C9 (e.g., warfarin).¹³⁷ Because of its linear and predictable pharmacokinetic properties, these interactions may sometimes be avoided or managed by using the lowest effective fluconazole dose. In patients with SOT or bone marrow transplantation, cyclophosphamide, tacrolimus, and sirolimus levels are increased if fluconazole is concomitantly administered.¹³⁹⁻¹⁴²

Itraconazole is subject to pH-based interactions and interactions involving CYP3A4 and P-gp. Drugs that can interact with itraconazole include agents that increase gastric pH (e.g., protonics) and lipophilic CYP3A4 (e.g., HMG-CoA reductase inhibitors, benzodiazepines, immunosuppressive agents), and/or P-gp substrates (e.g., digoxin) with poor oral availability.¹³⁷ Voriconazole is not affected by agents that increase gastric pH. However, CYP-mediated interactions involving voriconazole can involve drugs metabolized by CYP3A4 (e.g., midazolam, rifampin, phenytoin), CYP2C9 (e.g., warfarin), or CYP2C19 (e.g., omeprazole), and plasma levels of immunosuppressants are increased.^{137,143} Approximately 17% of a posaconazole dose undergoes biotransformation.¹⁴⁴ Unlike other azoles, posaconazole is only minimally (2%) metabolized by CYP; instead its metabolites are glucuronide conjugates formed via uridine diphosphate glucuronosyltransferase pathways.^{144,145} Although posaconazole is minimally metabolized by CYP, it inhibits hepatic CYP3A4.¹⁴⁶ Like the other azoles, the most clinically significant interactions associated with posaconazole involve benzodiazepines (oral midazolam), calcineurin inhibitors (cyclosporine, tacrolimus), other immunosuppressive agents (sirolimus), and phenytoin.¹³⁷ With more widespread use of posaconazole, the list of medications it interacts with will likely grow.

Isavuconazole acts as a moderate CYP3A4 inhibitor, and its clearance is highly dependent on CYP3A4 metabolism.¹²⁴

Drug interactions involving the azoles that are relevant to the ICU setting are summarized in Table 129-1.

Emergence of Resistance and the Selective Pressure of Azoles. Azole resistance in *Candida* spp. has been widely observed and studied—for example, fluconazole resistance in *C. albicans*. Resistant isolates of *Aspergillus fumigatus* were detected with a substitution of leucine for histidine in the cyp51A gene in combination with a 34-base pair tandem sequence in the promotor gene (TR/L98H) in patients and environmental isolates.¹⁴⁷⁻¹⁴⁹ The emergence of resistant *Candida* and *Aspergillus* raises concerns about the clinical relevance for patients at high risk of invasive fungal infection.

Echinocandin Antifungal Agents

Caspofungin, Micafungin, Anidulafungin

Pharmacology and Pharmacokinetics. The echinocandins are generally fungicidal and disrupt cell wall synthesis by inhibiting 1,3- β -D-glucan synthase. The echinocandins are active against *Aspergillus* and *Candida* spp. In addition, their spectrum of activity extends to *Pneumocystis jirovecii*. These agents have little or no activity against *H. capsulatum*, *B. dermatitidis*, or *C. neoformans*. The echinocandins are large lipopeptide compounds with poor enteral absorption and thus are not formulated for oral dosing. The individual echinocandins all demonstrate linear pharmacokinetic behavior. Each agent differs slightly in how it distributes throughout the body and how it is metabolized or degraded, although these differences are not clinically significant. The echinocandins are not appreciably metabolized by the cytochrome P450 enzyme system, but their interactions with drug transport proteins remain to be elucidated.

Caspofungin binds extensively to plasma proteins (primarily albumin). Caspofungin distribution is multiphasic; initially it distributes to plasma and extracellular fluid before being actively transported at a slow rate into the liver and other tissues via organic anion transport proteins.¹³⁷ The prolonged elimination half-life (8-13 hours) of caspofungin is due in part to this slow multiphasic distribution.¹³⁷ Caspofungin is slowly metabolized in the liver via *N*-acetylation and peptide hydrolysis to inactive metabolites, which are then excreted in bile and feces.¹⁵⁰ Average serum concentrations of caspofungin in surgical ICU patients 24 hours after administration vary greatly and are elevated above those seen in healthy subjects.¹⁵¹ Body weight and hypoalbuminemia were found to be prognostic factors responsible for these increased caspofungin concentrations.¹⁵¹ The clinical significance of such findings is unclear. Dosage adjustment is not required in patients with impaired renal function, but the dose should be reduced by 50% in patients with significant hepatic impairment.^{152,153} Micafungin distribution and metabolism are not fully understood. Following IV administration, micafungin binds extensively to albumin, but the significance of this interaction on drug activity is unclear.¹⁵⁴ Micafungin is hepatically metabolized to several metabolites, which along with parent drug, are eliminated in the feces. The pharmacokinetics are unaltered in renal dysfunction.^{154,155} Micafungin is a weak CYP3A4 inhibitor.¹⁵⁶

Anidulafungin distribution and metabolism are not fully understood. Of all the echinocandins, anidulafungin binds least to plasma proteins. It has a larger volume of distribution and achieves lower peak serum concentrations.^{157,158} Anidulafungin is not hepatically metabolized. Rather it undergoes slow nonenzymatic chemical degradation in the plasma to an inactive peptide breakdown product, which likely undergoes further enzymatic degradation and is excreted in feces and bile.¹⁵⁷ The majority of an anidulafungin dose is excreted in feces or urine as unchanged drug.¹⁵⁷

Toxicity and Drug Interactions. In general, echinocandins are well tolerated but are associated with nonspecific adverse effects (e.g., fever, headache, nausea, phlebitis, rash, elevated hepatic enzymes), which are generally mild and rarely cause early discontinuation of

therapy. Similarly, echinocandins have low potential to interact with other drugs, although interactions with cyclosporine and tacrolimus have been reported.¹³⁷

Pyrimidine Antifungal Agents

5-Fluorocytosine

Pharmacokinetics and Toxicity. 5-Fluorocytosine (5-FC, also called *flucytosine*) is a fluorinated pyrimidine related to 5-fluorouracil. It is the only agent in this therapeutic class. This antimycotic possesses a narrow spectrum of activity and is often associated with significant toxicity. Moreover, when used as monotherapy, resistance develops rapidly. Orally, 5-FC is nearly completely absorbed and distributes to total body water. Hepatic metabolism and protein binding are negligible. Nearly all is renally excreted as unchanged drug, and renal clearance is highly correlated with CrCl. Reductions in CrCl prolong the half-life of 5-FC.

Myelosuppression is the primary toxicity associated with 5-FC. In addition, it can cause significant rash, nausea, vomiting, diarrhea, and liver dysfunction. Flucytosine toxicity is associated with elevated drug concentrations and often occurs in the presence of renal dysfunction. Because 5-FC is primarily used in combination with amphotericin B, the effects of renal dysfunction on 5-FC pharmacokinetics and the subsequent risk of toxicity cannot be ignored.

Dosing and Therapeutic Drug Monitoring. Therapeutic drug monitoring for 5-FC is beneficial. Ideally, serum concentrations should be maintained between 25 and 100 μ g/mL to minimize toxicity and avoid the emergence of resistance. There are several nomograms for dosing 5-FC based on CrCl in patients with renal dysfunction. However, as they are based on serum creatinine measurements, they should only be used for patients with chronic renal dysfunction where the creatinine is not fluctuating rapidly. In addition, the nomograms should be used cautiously in elderly patients. During therapy, any necessary dosage adjustments should be made on the basis of plasma concentrations. Use of lower 5-FC doses (75-100 mg/kg/d) to minimize toxicity has been advocated. In vitro data suggest antifungal efficacy would not be compromised by such dosing.

IN VITRO SUSCEPTIBILITY TESTING OF SYSTEMIC ANTIFUNGAL AGENTS

In vitro susceptibility testing of *Candida* spp. is widely accepted. Standardized broth microdilution and disk diffusion methods developed by the Clinical and Laboratory Standards Institute (CLSI) and European Committee on Antimicrobial Susceptibility Testing (EUCAST) for in vitro susceptibility testing of *Candida* spp. are reproducible and accurate. Interpretative breakpoints for *Candida* spp. exist for fluconazole, itraconazole, voriconazole, 5-FC, the echinocandins, and posaconazole. For antifungal breakpoints, either CLSI or EUCAST provide data categorizing isolates into susceptible, resistant, and intermediate isolates.¹⁵⁹⁻¹⁶⁶ In contrast to *Candida* spp., in vitro susceptibility testing of *C. neoformans* is not routinely performed, because primary resistance to first-line antifungal drugs (5-FC, amphotericin B, fluconazole) is not currently a significant clinical problem. In addition, the susceptibility testing methods and interpretive breakpoints for *Cryptococcus* spp. with regard to any antifungal are not validated.¹⁶⁷ Validated broth microdilution methods for in vitro susceptibility testing methods of *Aspergillus* spp. for the azoles and amphotericin B have been developed, but interpretive breakpoints for these agents have not been established.¹⁶⁸ Validated agar-based disk diffusion methods and commercial kits (Etest) are available and may be reliable methods for determining susceptibilities of *Aspergillus* spp.¹⁶⁸ Although broth microdilution methods for susceptibility testing of *Aspergillus* spp. for the echinocandins exist, the minimum inhibitory concentration is not the ideal measure of drug activity for this class of agents.¹⁶⁸ The EUCAST Subcommittee on Antifungal Susceptibility Testing determined breakpoints based on pharmacokinetic and

TREATMENT OF FUNGAL INFECTIONS IN THE CRITICALLY ILL

Candidiasis in the ICU

There are many options for empiric therapy of fungal infections in the ICU. For many years, the poor prognosis associated with invasive candidiasis fueled widespread use of antifungal agents, particularly fluconazole, in ICU patients with or without an established source of fungal infection.

The paradigms of preventive antimycotic therapy are prophylaxis and empiric or preemptive therapy. Prophylaxis is generally regarded as the initiation of treatment for all patients in a population in anticipation of certain risk factors, regardless of whether they ever manifest. There are few data to justify the use of this paradigm in the ICU setting,^{169,170} where concerns regarding selection of resistant fungal pathogens with indiscriminate antifungal use persist.¹⁷¹ Moreover, the risk for invasive candidiasis is not the same for all ICU patients, and some risk factors evolve during an ICU stay. Therefore, universal institution of antifungal prophylaxis in the general ICU population is generally discouraged in favor of a more targeted approach selectively directed toward those patients at the highest risk.^{169,171} *Empiric treatment* or a fever-driven approach describes the situation of a patient at risk for invasive candidiasis who has a persistent fever but no other symptoms or microbiological evidence of a specific infection.

Preemptive therapy is the administration of antifungal treatment before the occurrence of a septic syndrome in patients with several known risk factors for infection and evidence of significant *Candida* colonization.¹⁷¹ Historically, AmB-d was the sole option for prevention or treatment of candidiasis in the ICU setting. However, the risk of nephrotoxicity and the advent of safe and effective alternatives such as the echinocandins have diminished its use in the ICU.

Prophylaxis

Most studies of prophylactic antifungal use in the ICU setting have evaluated fluconazole. A placebo-controlled study for the prevention of intraabdominal *Candida* infections in a selected group of high-risk abdominal surgical patients showed that daily fluconazole (400 mg) significantly reduced the incidence of invasive candidiasis.¹⁷² This study included patients who had recurrent gastrointestinal perforations or anastomotic leaks; therefore, they were at very high risk of developing intraabdominal candidiasis. The patients in this study had moderate acuity (APACHE II score 13), but prophylactic fluconazole prevented *Candida* colonization and dissemination of *Candida* spp. Similar to experiences with HSCT recipients, this study illustrates that when the prophylactic paradigm is selectively applied, it may benefit specific patient populations. This has also been shown in patients with HSCT.^{172,173} Similar results were obtained in critically ill surgical patients staying in the ICU longer than 3 days.^{117,174} However, these results should be interpreted cautiously. This was a single-center study, and true to the paradigm, patient selection was somewhat subjective and based on an anticipated ICU stay of 3 or more days and the clinician's experience. Therefore, the results may not be widely generalizable. Others have also prospectively studied prophylactic fluconazole and shown an advantage for low-dose IV fluconazole (100 mg/d) in reducing *Candida* colonization and candidemia, but with no effect on either invasive candidiasis or overall mortality.¹⁷⁵ In this double-blind randomized placebo-controlled study, all patients received selective digestive decontamination. The incidence of *Candida* infections, particularly candidemia, was significantly less in the fluconazole-treated patients.

Using these three studies and others that included ketoconazole or nonabsorbable antifungal agents, three meta-analyses have attempted

to provide further insight into the role of antifungal prophylaxis in critically ill patients but with disparate results. One analysis concluded that prophylactic fluconazole administration to prevent mycoses in surgical ICU patients successfully decreased the rate of fungal infections, but it did not improve survival.¹⁷⁶ Conversely, a second analysis demonstrated that antifungal prophylaxis indeed reduced the risk of candidemia and resulted in a reduction of overall mortality and attributable mortality (31% and 79%, respectively).¹⁷⁷ The third and perhaps most rigorous meta-analysis demonstrated that antifungal prophylaxis in nonneutropenic critically ill patients reduces proven invasive fungal infections by approximately half and total mortality by approximately one-quarter.¹⁶⁹ Although the analyses had slightly differing results, all concluded that if antifungal prophylaxis is employed, it should be done so selectively and targeted toward those patients at high risk of developing infection.^{169,176,177} Thus, what the prophylactic studies have highlighted is the need to identify high-risk patients for empiric or preemptive therapy.

Empiric Therapy

Empiric therapy is defined as a fever-driven approach in a persistently febrile patient at risk for invasive candidiasis but without microbiological proof of infection. Early treatment of presumed candidemia is favored as it is associated with higher survival rates. However, current clinical trials have not shown statistically significant prevention of invasive candidiasis.^{18,51,52} The optimal time to start empiric antifungal therapy remains unclear. The choice of the antifungal administered should be based on local epidemiology and currently administered drugs (interactions).

Preemptive Therapy

There are few randomized prospective data addressing preemptive therapy, a diagnosis-driven approach. In the absence of mechanisms to identify patients who would most benefit by preemptive antifungal therapies, this strategy shares similar drawbacks to the prophylactic strategy. However, a growing body of data clearly demonstrates the importance of early institution of antifungal therapy in the adult ICU.^{31,33,34,37,38,178} There are a number of predictive rules of varying complexity described in the literature. All of the studies have produced different predictive algorithms; few have been prospectively validated.⁴⁹ While the methods are improving, published methods have yet to be widely applied in ICU patients as part of routine practice. Moreover, there are few data describing the outcomes associated with preemptive therapy instituted based upon a predictive rule. One small study assessed the use of a scoring system to identify high-risk patients and demonstrated that fluconazole significantly decreased the incidence of invasive candidiasis in patients with a corrected colonization index (CCI) of ≥ 0.5 .¹⁷⁹ Another prospective study to assess whether preemptive antifungal therapy would reduce invasive candidiasis in high-risk ICU patients (CCI ≥ 0.4) demonstrated a significant decrease in the incidence of surgical ICU-acquired invasive candidiasis with preemptive therapy compared to historic controls.¹⁸⁰ However, to generate the CCI, required weekly surveillance cultures at multiple anatomic sites in all ICU patients is necessary. This method is not practical for most ICUs, and it is doubtful that the CCI could be used with similar success without routine surveillance cultures.⁴¹ The serologic detection of 1,3- β -D-glucan, which is not specific for *Candida* spp., is a useful tool for ruling out invasive fungal infection.¹⁷

With the exception of fluconazole, there are few prospective data assessing the efficacy of other antifungal agents as preemptive therapy in the ICU. Administering itraconazole capsules through feeding and nasogastric tubes, which are often placed in ICU patients, is difficult. Although the oral solution solves this problem, there are few data assessing its effectiveness in preventing or treating invasive candidiasis. Furthermore, the use of itraconazole in critically ill patients is also limited by a significant drug-drug interaction profile with agents commonly used in the ICU.

The recommended antifungal therapy for candidiasis in the ICU setting is summarized in Table 129-2.

TABLE 129-2 Summary of Recommended Antifungal Therapy for Aspergillosis, Candidiasis, and Mucormycosis in the ICU Setting

| Infection | Recommended Treatment | Alternative Treatment |
|--|---|--|
| INVASIVE ASPERGILLOSIS | | |
| Targeted Therapy | VCZ, 6 mg/kg IV q 12 h for 1 day, followed by 4 mg/kg q 12 h; oral dose is 200 mg q 12 h <i>or</i> ISA, 200 mg TID IV for 2 days, followed by 200 mg/d IV thereafter | Consider, if prior azole exposure, LAmB, 3 mg/kg/d IV Caspofungin, 70 mg IV on day 1 and 50 mg/d IV thereafter |
| Empirical therapy (fever-driven approach) | Caspofungin, 70 mg IV on day 1 and 50 mg/d IV thereafter | |
| Prophylaxis against invasive aspergillosis | PCZ tablet, 300 mg BID PO on day 1 and 300 mg/d PO thereafter PCZ, 300 mg BID IV on day 1 and 300 mg/d IV thereafter in patients unable to swallow | |
| INVASIVE CANDIDIASIS (CANDIDEMIA) | | |
| Treatment (non-neutropenic patients) | Echinocandin-Anidulafungin, 200 mg IV on day 1 and 100 mg/d IV thereafter, <i>or</i> caspofungin, 70 mg IV on day 1 and 50 mg/d IV thereafter, <i>or</i> micafungin, 100 mg/d IV. Consider local epidemiology (<i>C. parapsilosis</i> , <i>C. krusei</i>) and susceptibility testing: if <i>C. parapsilosis</i> switch to FCZ, 400 mg/d IV. | LAmB, 3 mg/kg/d, <i>or</i> VCZ, 6 mg/kg IV q 12 h for 1 day, followed by 4 mg/kg q 12 h; oral dose is 200 mg q 12 h |
| Alphabetical order | | |
| Treatment (neutropenic patients) | Caspofungin, 70 mg IV on day 1 and 50 mg/d IV thereafter, <i>or</i> micafungin, 100 mg/d IV | Anidulafungin, 200 mg IV on day 1 and 100 mg/d IV thereafter, <i>or</i> LAmB, 3 mg/kg/d. FCZ, 400 mg/d IV, should be used as step-down only. |
| Suspected candidiasis treated with empirical antifungal therapy (non-neutropenic patients) | Early treatment for suspected candidiasis is associated with higher survival. However, due to lack of data no specific drug can be recommended. Choose according to local epidemiology, administered drugs (interactions) from antifungals recommended for candidemia. | |
| Suspected candidiasis treated with empiric antifungal therapy (neutropenic patients) | LAmB, 3 mg/kg/d, <i>or</i> caspofungin, 70 mg IV on day 1 and 50 mg/d IV thereafter | Micafungin, 100 mg/d IV, <i>or</i> VCZ, 6 mg/kg IV q 12 h for 1 day, followed by 4 mg/kg q 12 h; oral dose is 200 mg q 12 h |
| Prophylaxis | FCZ, 400 mg/d, while patients are at high risk | Micafungin, 50 mg/d IV; caspofungin, 70 mg IV on day 1 and 50 mg/d IV thereafter |
| MUCORMYCOSIS | | |
| Targeted therapy | LAmB, (5-) 10 mg/kg/d* IV | ISA, 200 mg TID IV for 2 days, followed by 200 mg/d IV thereafter PCZ, 300 mg BID IV on day 1 and 300 mg/d IV thereafter |
| Prophylaxis | PCZ tablet, 300 mg BID PO on day 1 and 300 mg/d PO thereafter | |

*Consider increasing dosages for extensive disease if renal function is adequate.

BID, twice daily; FCZ, fluconazole; ISA, isavuconazole; ITZ, itraconazole; IV, intravenous; LAmB, liposomal amphotericin B; PCZ, posaconazole; PO, per os; TID, 3 times a day; VCZ, voriconazole.

Invasive Aspergillosis, Mucormycosis, and Other Opportunistic Mycoses in Bone Marrow Transplantation

Fever and neutropenia are common among critically ill immunocompromised individuals with hematologic malignancies. Although fever can be due to many causes, these patients, particularly those with leukemia or HSCT recipients, are at risk of developing invasive fungal infections due to *Candida*, *Aspergillus* spp., or Mucorales. Owing to the difficulty in diagnosing infections due to these pathogens, antifungal prophylaxis is standard in HSCT patients. Fluconazole has been shown to decrease the incidence of invasive infections with *Candida* spp. and is widely used in the prophylactic paradigm.¹⁷² As stated previously, invasive aspergillosis occurs relatively late after transplantation. Therefore, persistently febrile HSCT recipients should be treated empirically with antifungal agents with activity against molds, particularly *Aspergillus* spp.

For many years, high-dose AmB-d was employed as standard empiric therapy of invasive aspergillosis, but within the past decade, based upon data from a randomized trial that compared voriconazole to AmB and suggested superiority with the azole, voriconazole has been considered the gold standard therapy for documented and suspected aspergillosis.¹⁸¹ Although voriconazole is considered an initial option for prophylaxis, the choice of therapy may vary depending on the individual's organ function. Voriconazole may not be ideal in cases where liver disease is present or if the patient is being treated concomitantly with medicines that interact with this azole. Similarly, the presence of reduced renal function may preclude the use of lipid amphotericin B formulations. Fluconazole lacks activity against molds. Itraconazole has activity against *Aspergillus* spp., but as discussed previously, the capsule dosage form is not suitable for many critically ill patients and produces erratic blood levels. The oral solution of itraconazole is not well tolerated and is commonly associated with diarrhea. Even if available, IV itraconazole suffers the same

drawback as lipid amphotericin B formulations in patients with diminished renal function. With the new tablet and IV formulations, posaconazole can be administered to critically ill patients independent of food intake.

The latest clinical data on isavuconazole shows noninferiority and better tolerability in comparison with voriconazole for the treatment of invasive aspergillosis.¹³³ With their lack of toxicity and low propensity for drug-drug interactions, the echinocandins are also promising agents for empiric therapy of invasive aspergillosis in critically ill patients.

Patients with profound immunosuppression are at risk for mucormycosis, and targeted treatment differs considerably from therapy of invasive aspergillosis. While surgery is an integral part of therapy, as it decreases mortality, initiation of high-dosage liposomal amphotericin B or isavuconazole appears warranted.^{82,84,133,134,182} The combination of isavuconazole or posaconazole with high-dose LAmB may be needed in patients with extensive disease.^{82,84}

Recommended antifungal therapy for the treatment of invasive aspergillosis and mucormycosis in the ICU setting is summarized in Table 129-2.

Cryptococcosis, Histoplasmosis, and Blastomycosis

Although cryptococcosis, histoplasmosis, blastomycosis, and coccidioidomycosis are not considered nosocomial mycoses, patients with severe infections with these organisms may require intensive care. Recommended antifungal therapy for treatment of these three organisms in the ICU setting is summarized in Table 129-3. The treatment of cryptococcosis, particularly in the CNS, evolved from a series of classic clinical trials. Current guidelines base their recommendations on the best data available to address unresolved questions surrounding treatment of this infection.

Management of Increased Intracranial Pressure in CNS Cryptococcosis

Elevations in intracranial pressure (ICP) occur in more than half of patients with cryptococcal meningitis and contribute significantly to the morbidity and mortality associated with this infection.¹⁵⁷ Most data on the management of acutely elevated ICP have been derived from studies of patients with AIDS. Therefore, ICP management may be

TABLE 129-3

Summary of Recommended Antifungal Therapy for Cryptococcosis and Endemic Mycoses in the ICU Setting

| INFECTION | RECOMMENDED TREATMENT(S) | ALTERNATIVE TREATMENT |
|--|--|---|
| CRYPTOCOCCOSIS | | |
| CNS infection (HIV infected): antiretroviral therapy should be delayed to avoid immune reconstitution syndrome | Induction: AmB-d, 0.7-1 mg/kg/d IV, + 5-FC, 100 mg/kg/d PO, or L-AmB, 3-6 mg/kg/d IV, or ABLC, 5 mg/kg/d IV, + 5-FC, 100 mg/kg/d PO for 4-6 wk. Consolidation therapy: FCZ or ITZ, 400 mg/d PO for 8 wk, followed by maintenance with FCZ, 200 mg/d PO, if disease free and CD4 count >200 μ /l | AmB-d, 0.7-1 mg/kg/d IV, + FCZ, 800 mg/d PO FCZ, \geq 800-1200 mg/d PO favorable, + 5-FC, 100 mg/kg/d PO |
| CNS infection (transplant recipient) | Induction therapy: LAmB, 3-6 mg/kg/d IV, or ABLC, 5 mg/kg/d IV, + 5-FC, 100 mg/kg/d PO for at least 2 wk. Consolidation therapy: FCZ, 400-800 mg/d PO for 8 wk. Maintenance therapy: FCZ, 200-400 mg/d PO for 6 mo-1 y | LAmB, 6 mg/kg/d, or ABLC, 5 mg/kg/d for 4-6 wk |
| CNS infection (non-HIV positive, nontransplant recipient) | Induction: AmB-d, 0.7-1 mg/kg/d IV, + 5-FC, 100 mg/kg/d PO for at least 4 wk, or AmB-d, 0.7-1 mg/kg/d IV for \geq 6 wk, or LAmB, 3-6 mg/kg/d IV, or ABLC, 5 mg/kg/d IV, + 5-FC, 100 mg/kg/d PO, if possible \geq 4 wk, or AmB-d, 0.7 mg/kg/d IV, + 5-FC, 100 mg/kg/d PO for 2 wk. Consolidation therapy: FCZ, 400-800 mg/d PO for 8 wk. Maintenance therapy: FCZ, 200 mg/d PO for 6 mo-1 y | |
| HISTOPLASMOSIS | | |
| Acute pulmonary (moderately severe to severe) | LAmB, 3-5 mg/kg/d IV, or AmB, 0.7-1 mg/kg/d IV for 1-2 wk, \pm corticosteroids, then ITZ, 200 mg PO BID for 12 wk | |
| Progressive disseminated histoplasmosis (moderately severe to severe) | LAmB, 3-5 mg/kg/d IV, or ABLC, 5 mg/kg/d IV; or AmB-d, 0.7-1 mg/kg/d IV for 1-2 wk; followed by ITZ, 200 mg PO BID for at least 1 y | |
| BLASTOMYCOSIS | | |
| Pulmonary (moderately severe to severe) | LAmB, 3-5 mg/kg/d IV, or AmB-d, 0.7-1 mg/kg/d IV, until clinical improvement; followed by ITZ, 200 mg PO BID for 6-12 mo | |
| EXTRAPULMONARY (DISSEMINATED) | | |
| CNS | LAmB, 5 mg/kg/d IV until clinical improvement, followed by an oral azole for at least 1 y (e.g., FCZ, 400-800 mg/d PO, or ITZ, 200 mg PO BID) | |
| Non-CNS (moderately severe to severe) | LAmB, 3-5 mg/kg/d IV, or AmB-d, 0.7-1 mg/kg/d IV for 1-2 wk, followed by ITZ, 200 mg PO BID for 12 mo | |

underutilized in patients with CNS cryptococcosis who are HIV-negative. Persistent elevations in ICP should be managed by sequential lumbar punctures.¹⁵⁷ If necessary, more invasive procedures, including insertion of a lumbar drain or placement of a ventriculoperitoneal shunt, should be performed.¹⁵⁷ The frequency with which lumbar punctures are performed depends on the initial opening pressure and symptoms. For patients with elevated baseline opening pressure, the pressure should be reduced by 50%, with subsequent lumbar puncture performed daily to maintain the ICP in the normal range.¹⁵⁷

Serum and CSF antigen titers are important in establishing the presumptive diagnosis and assessing the prognosis of CNS infection. The test measures cryptococcal polysaccharide capsule antigens but does not differentiate viable from nonviable organisms. Therefore, once therapy is started, treatment decisions should not be based on antigen test results.¹⁵⁷ A reduction in antigen titers during therapy is desired, but treatment decisions should be based on culture results.

Treatment of Histoplasmosis in Critically Ill Patients

Although there are no comparative studies, the efficacy of individual antimycotics for therapy of chronic and disseminated histoplasmosis has been well documented. AmB-d and itraconazole have proven efficacy. The efficacy of 6 weeks to 4 months of AmB-d therapy for chronic infection is approximately 75%; however, relapse is common. The efficacy of itraconazole ranges from 75% to 85%, but as is the case for AmB-d, relapse may be common. In vitro susceptibility of *H. capsulatum* to fluconazole is poor, and it is generally not used to treat this infection. Voriconazole and posaconazole are likely effective in the treatment of histoplasmosis, but data assessing their safety or efficacy for this infection are lacking.

The efficacy of AmB-d for therapy for disseminated histoplasmosis among immunocompetent patients is 70% to 90%. Therefore, AmB-d is recommended initially in severely ill patients. In a small study, all patients responded to itraconazole, 200 to 400 mg daily.¹⁸³ Once an adequate response is noted to AmB-d, therapy can be switched to itraconazole.¹⁸³ Few data exist concerning the efficacy of the lipid amphotericin B formulations as therapy for disseminated histoplasmosis in immunocompetent patients.

Treatment of Disseminated (Extrapulmonary) Blastomycosis in the Critically Ill

Disseminated blastomycosis and diffuse pulmonary infection are both associated with significant mortality. Treatment of these infections

produces cure rates ranging from 85% to 90%, and the effective agents cause little associated toxicity.⁹⁷ The optimal duration of therapy for the treatment of blastomycosis with existing antifungal agents is unknown and has been empirically derived from noncomparative studies and clinical experience. In cases of life-threatening infections or extrapulmonary disease and in patients who are severely immunocompromised or have already failed therapy with an azole, the risk of relapse is high.⁹⁷ Therefore, the duration of treatment is lengthy to prevent relapse. Patients can be switched to safer azole therapy when significant improvement is observed.⁹⁷

CONCLUSION

Invasive fungal infections are widespread in critically ill patients. Specifically in the ICU setting, *Candida* spp. are a common cause of nosocomial BSIs. There are many risks associated with the ICU environment or patients' underlying disease states that predispose them to infections with these pathogens. In addition, historically, because of the high mortality associated with BSIs caused by *C. albicans*, this species has been the primary fungal pathogen of concern. Although the epidemiology of *Candida* isolates in the ICU continues to shift, whether the changing epidemiology is a consequence of injudicious antifungal use is a matter of speculation and debate. Nonetheless, the steady increase in BSIs due to *C. glabrata*, a species with reduced susceptibility to antifungal therapy, is concerning. Furthermore, select populations of critically ill patients are at risk of developing life-threatening infections due to *Aspergillus* spp., *Fusarium* spp., and the Mucorales. These pathogens are angioinvasive and often respond poorly to antifungal therapy. The endemic mycoses (histoplasmosis, blastomycosis, and coccidioidomycosis) are not typically a concern in the ICU setting, but patients with severe infections due to *B. dermatitidis*, *H. capsulatum*, or *C. immitis* will often require intensive care.

Methods to perform antifungal susceptibility tests on a variety of pathogens, particularly *Candida* spp., are becoming routine in clinical practice. There is improved understanding of antifungal resistance and the pharmacodynamic actions of antifungal drugs. This understanding may ultimately lead to more rational use of antifungal agents and improved outcomes in infected patients. The advent of additional safer agents means that the available drugs differ sufficiently in terms of toxicity and potential for drug-drug interactions that clinicians have the luxury of choice when tailoring antifungal therapy to a specific patient.

KEY POINTS

Overview

1. Generally, fungal infections are more prevalent in ICUs than on the general medical wards. Although *Candida* spp. are the most commonly isolated fungi in critically ill patients, infections caused by other opportunistic fungal pathogens (i.e., *Aspergillus*, *Cryptococcus neoformans*, *Fusarium*, and Mucorales) are also a concern in selected critically ill populations.
2. New antifungal agents differ in mode and spectrum of activity, toxicity, and propensity to interact with other drugs. Antifungal therapy has to be tailored to the specific fungal pathogen and the needs of the patient.

Fungal Infections in the Critically Ill

1. *C. albicans* is the primary fungal pathogen in the ICU setting, but the prevalence of a given species may vary with age. For example, candidemia among neonates is predominantly due to *C. albicans*

and *C. parapsilosis*, rarely *C. glabrata* or other *Candida* spp. In adults, *C. albicans* and *C. glabrata* predominate.

2. Age differences in the isolation of specific species may have important repercussions for infection control, dosing, and selection of antifungal agents in older critically ill patients.
3. Bloodstream infections (BSIs) due to *C. glabrata* continue to become more prevalent.
4. In the ICU, *Candida* BSIs are common and difficult to detect, and consequently they carry a relatively poor prognosis. Although isolation techniques have improved, the attributable mortality rate associated with *Candida* BSIs is 35%, and *Candida* spp. are the only BSI pathogens that are an independent predictor of mortality. In surviving patients, candidemia adds approximately 1 month to the length of hospital stay.
5. Critically ill patients with hematologic malignancies are at high risk for infections due to *Candida*, *Aspergillus* spp., and

KEY POINTS—cont'd

Mucorales. Infections due to these pathogens are associated with high mortality.

Systemic Antifungal Agents

1. Amphotericin B deoxycholate (AmB-d) possesses a broad spectrum of activity and a long history of use with little acquired resistance, but its toxicity is significant, and it is potentially costly. In low doses for short courses, this agent is tolerable.
2. Lipid amphotericin B formulations are safer than AmB-d, but their cost may limit their use.
3. Azoles possess a broad spectrum of activity and are relatively safe, but they interact with a vast array of drugs that are commonly used in ICU populations.
4. Echinocandins are safe and interact with few drugs, but their spectrum of activity is limited primarily to *Candida* and *Aspergillus* spp.

Treatment of Fungal Infections in the Critically Ill

1. The paradigms of preventive antifungal therapy are prophylaxis, empiric, and preemptive therapy. There are few data to help

choose among these three approaches. *Empiric therapy* is the administration of antifungals to patients with persistent fever as the only symptom of a potential fungal infection. *Preemptive therapy* is the administration of antifungal treatment before the appearance of sepsis syndrome in patients with risk factors for infection and evidence of significant *Candida* colonization.

2. The treatment of CNS cryptococcosis evolved from a series of classic clinical trials. Elevations in intracranial pressure (ICP) occur in more than 50% of patients and contribute significantly to the morbidity and mortality of this infection. Therefore, in addition to antifungal therapy, elevations in ICP should be managed by sequential lumbar punctures. Serum and cerebrospinal fluid antigen titers aid in the presumptive diagnosis and assessing the prognosis of infection. A reduction in antigen titers during therapy is desired, but treatment decisions should be based on culture results.

Wey SB, Mori M, Pfaller MA, Woolson RF, Wenzel RP. Risk factors for hospital-acquired candidemia: a matched case-control study. *Arch Intern Med*. 1989;149:2349-2353.

This study was one of the first rigorous epidemiologic assessments of the risk factors that predispose patients to candidemia. Established risk factors have been borne out in subsequent analyses.

Pittet D, Li N, Woolson RF, Wenzel RP. Microbiological factors influencing the outcome of nosocomial bloodstream infections: a 6-year validated, population-based model. *Clin Infect Dis*. 1997;24:1068-1078.

This article provides compelling data concerning the importance of Candida spp. as bloodstream pathogens, as well as data regarding the crude and attributable mortality rates of Candida BSLs in the hospital. The study demonstrates that of all the microbial causes of BSLs, only Candida spp. are an independent predictor of mortality due to BSL.

Garey KW, Rege M, Pai MP, et al. Time to initiation of fluconazole therapy impacts mortality in patients with candidemia: a multi-institutional study. *Clin Infect Dis* 2006;43:25-31.

Inadequate antimicrobial treatment is an independent determinant of hospital mortality, and in companion publications, this group demonstrated the most common causes of inappropriate therapy for fungal BSLs are omission of initial empiric therapy and incorrect dosing of fluconazole. In this work, the authors link inadequate therapy to mortality. They demonstrate that delays in initiation of therapy of more than 24 hours were independently associated with mortality in patients with candidemia. The rate of development of newer and more potent antifungal agents is tailing off. Thus, this work, which has subsequently been corroborated, illustrated that current antifungal agents, if used properly, can perhaps help reduce mortality more than realized to date. In addition, it calls attention to the need to focus on early appropriate therapy as a strategy to reduce the significant mortality associated with candidemia.

Golan Y, Wolf MP, Pauker SG, Wong JB, Hadley S. Empirical anti-*Candida* therapy among selected patients in the intensive care unit: a cost-effectiveness analysis. *Ann Intern Med*. 2005;143:857-869.

Few studies have prospectively evaluated antifungal prophylaxis, and meta-analyses of these studies all produce slightly different conclusions. However, the meta-analyses all agree that in the ICU, targeted empiric therapy directed at high-risk ICU patients is probably a better strategy than general prophylaxis. However, even fewer studies have prospectively evaluated empiric therapy directed at high-risk ICU patients. This study provides a decision analytic model to evaluate the cost-effectiveness of empiric anti-Candida therapy given to such patients, defined as those with altered temperature (fever or hypothermia) or unexplained hypotension despite 3 days of antibacterial therapy in the ICU. In doing so, they found that although empiric caspofungin was the most effective strategy, it did not reduce mortality at an acceptable cost. Empiric amphotericin B, regardless of formulation, was the least effective strategy, owing to drug toxicity. The most effective strategy was empiric fluconazole because it reduced mortality at an acceptable cost.

Maertens JA, Raad II, Marr KA, et al. Isavuconazole versus voriconazole for primary treatment of invasive mould disease caused by *Aspergillus* and other filamentous fungi (SECURE): a phase 3, randomised-controlled, non-inferiority trial. *Lancet* 2016;387(10020):760-769.

This was a phase 3, double-blind, multicenter, comparative-group study. Patients with suspected invasive mold disease were randomized in a 1:1 ratio to receive isavuconazonium sulfate or voriconazole. Isavuconazole was noninferior to voriconazole for the primary treatment of suspected invasive mold disease, was well tolerated, and had fewer drug-related adverse events.

Influenza is a zoonosis indigenous to waterfowl, with periodic introduction of the virus into domesticated poultry, humans, and other mammals. The consequences of host species transfer from birds to humans can be devastating, with substantial mortality rates and rapid transmission by the respiratory route with a potential for a global pandemic. The fate of influenza virus infection in human populations depends upon the virus virulence properties, immunologic differences from previous influenza outbreaks, fitness of the virus for replication and dissemination within humans, and status of the host immune defenses.¹

In the winter months, severe disease in individual patients is usually limited to those with vulnerabilities in host defenses, including the very young, the very old, and individuals with immunodeficiency or an underlying cardiopulmonary disease. The annual incidence rate varies each season depending upon the degree of antigenic "drift" (point mutations in coding regions of genes for major surface antigens) from one year to the next. However, influenza pandemics can occur following an antigenic "shift" (i.e., whole-scale reassortment of the influenza virus genome, with the expression of entirely new antigenic components), and these novel influenza hybrid viruses circulate throughout the susceptible global population. This set of events occurred in 2009 with the novel swine influenza virus strain, where almost everyone, including healthy young people, became susceptible to this new influenza infection and its complications.²

Even in a typical nonpandemic year, influenza viruses account for the deaths of hundreds of thousands of people worldwide and exact billions of dollars from society in terms of morbidity and lost productivity. Recent estimates from the United States indicate that at least 610,660 life-years are lost, with 3.1 million hospital days, 31.4 million outpatient visits, and \$10.4 billion in direct medical costs annually from influenza alone. The staggering amount expended for influenza care is \$16.3 billion in projected lost earnings and an estimated total cost burden (including lost-life years) amounting to \$87.1 billion.³ The global costs to society during a rather mild pandemic year such as 2009 have been estimated to be about \$374 billion.⁴ The costs of intensive care services required for managing the most severely ill influenza victims alone are enormous.²

PATHOGENICITY OF INFLUENZA VIRUSES

Influenza virus is a single-stranded RNA virus of the family *Orthomyxoviridae*. It affects birds and mammals and includes three genera, influenza virus A, B, and C, based upon their matrix proteins.^{1,5} Influenza A virus is more likely to reassort its genome with bird and mammal influenza viruses and has the greatest pandemic potential. Based upon the antibody response to two major antigenic proteins on the surface of the virus, hemagglutinin (HA) and neuraminidase (NA), influenza A is subdivided into different serotypes including H1N1 (responsible for Spanish flu in 1918, in addition to the 2009 flu pandemic), H2N2 (Asian flu of 1957), H3N2 (Hong Kong flu in 1968), H5N1 (the avian flu, often cited as the most recent pandemic threat), and H7N9, which circulated in China in 2012. A number of other influenza virus types are circulating in birds and mammals (H7N7, H1N2, H9N2, H7N2, H7N3, and H10N7). The two other forms include influenza B (which almost exclusively infects humans and

lacks pandemic potential) and influenza C (affecting humans, dogs, and pigs), which only rarely cause severe illness and epidemics in humans.⁶

The genome of influenza A virus consists of eight separate single-strand segments, each encoding a single major viral protein. The single-stranded RNA-based genome provides a high background mutation rate and gives the virus genetic plasticity. The multiple genome segments permit reassortment of large sequences of RNA, resulting in hybrid viruses when hosts are infected simultaneously by more than one virus strain. These events lead to the evolution of entirely novel viruses with new antigenic constituents (antigenic shift). As an example, the novel swine-origin influenza A/Mexico City/4/2009 (H1N1) outbreak strain was a quadruple-reassorted virus derived from gene segments originating from ducks, Eurasian swine, North American swine, and human-adapted influenza virus.⁷

Avian-adapted viruses can occasionally be transmitted to mammals, causing outbreaks in animals or giving rise to disease in human pandemics. Pigs are important "mixing vessel" hosts in shuttling avian influenza viruses to humans as they can carry both avian- and human-adapted influenza viruses.¹ Porcine mucous membranes express a mixture of sialic acid-coated glycopeptides linked in a favorable conformation to bind both avian- and human-adapted viruses. This is vitally important in the biology of influenza viruses as the initial event in influenza infection is an interaction of the HA receptor to binding sites on host epithelial tissues. Avian species primarily express α 2,3-linked sialic acid-galactose disaccharides on their epithelial surfaces, and avian-adapted influenza viruses preferentially bind to this linkage pattern. The human upper airways primarily express α 2,6-linked sialyl-galactose surface receptors, and seasonal influenza strains in humans bind readily only to α 2,6 linkages. Pigs, in contrast, normally express both α 2,3- and α 2,6-linked disaccharides on their mucous membranes. This biochemical arrangement facilitates simultaneous dual infections with avian- and human-adapted viruses and the attendant risk of hybrid viruses.^{1,7,8}

The lower airways and alveolar pneumocytes of humans actually express α 2,3-linked sialylated glycopeptides, and viruses that bind efficiently to α 2,3 linkages can cause severe pneumonia if deposited into the distal airways. Most seasonal influenza strains bind preferentially to α 2,6-linked disaccharide HA binding sites found in human upper airways. This usually leads to high transmission frequency by airborne droplet nuclei deposited into the upper airways but a relatively low risk of primary influenza pneumonia.⁹ The avian strain of H5N1 preferentially binds to α 2,3 linkages and is therefore poorly transmissible from person to person, but it has the potential to cause severe pneumonia if delivered to the lower airways. Poultry workers in Asia in close proximity to infected livestock can occasionally receive enough viruses deposited into the distal airways to cause severe influenza pneumonia with a high mortality rate (50%-70%).^{9,10}

Notably, the severe 1918 pandemic strain of H1N1 influenza expressed an HA that could bind with high affinity to both α 2,6- and α 2,3-linked sialyl-galactose moieties.^{11,12} The result of this unusual HA binding affinity was a highly transmissible virus with the capacity to replicate and spread in the upper airways and cause severe disease in the lower airways. Disturbingly, the HA of the 2009 outbreak strain of novel swine origin also bound with high affinity to both α 2,6 and α 2,3

TABLE 130-1 Pathogenicity Traits and Virulence Factors of Influenza Viruses

| VIRAL TRAIT | MECHANISM OF VIRULENCE | COMMENTS |
|---------------------------------|---|---|
| Epitope variations on HA and NA | Immune escape from recognition by preexisting antibodies within the population from previous virus exposure | Antigenic drift (point mutations) leads to epidemics; antigenic shift (reassorted genomes) leads to pandemics |
| Cleavability of HA | HA undergoes proteolysis by host-derived proteases before receptor binding | Readily cleaved HA is associated with avid binding and disease severity |
| Binding preference of HA | α 2,3-linked sialic acid receptor in alveoli and α 2,6 linkage in upper airways | Viruses that bind to the α 2,3 linkage or both α 2,3 and α 2,6 are more virulent |
| HA:NA ratio | NA cleaves sialic acid on glycopeptides on epithelium (binding site for HA) | Optimal ratio of NA and HA activity needed for high replication and release |
| NS-1 | This nonstructural protein inhibits host-derived interferons | Mutation or truncated variants are associated with loss of virulence |
| PB1-F2 | This peptide targets virus trafficking to mitochondria and induces apoptosis | Mutations or truncated forms of PB1-F2 associated with loss of virulence |
| NA inhibitor resistance | H275Y mutation blocks NA inhibitor binding site and oseltamivir activity | Commonly seen mutation is seasonal H1N1 but rare in the 2009 outbreak strain |
| M2 inhibitor resistance | S31N mutation blocks activity of amantadine | Now commonplace in both H3N2 and H1N1 |
| PB2 temperature range | Polymerase activity at lower (mammals) and higher (avian) temperature | Broad Pol temperature range aids transfer from bird to human hosts |

H275Y, histidine substitution for tyrosine at amino acid at position 275; HA, hemagglutinin; M, matrix protein; NA, neuraminidase; NS-1, nonstructural protein; PB, polymerase basic; Pol, polymerase; S31N, serine substitution for asparagine at amino position 31.

linkages. Fortunately, the virulence factors of the influenza virus (Table 130-1) resulted in an overall low case-fatality rate (<0.1%). A further mitigating factor against mortality in older populations during the 2009 outbreak was the presence of preexisting memory cells with B- and T-cell epitope recognition sites in people born before the early 1950s, induced by other H1N1 viruses circulating in the first half of the 20th century.¹³

CLINICAL MANIFESTATIONS AND COMPLICATIONS OF INFLUENZA

Classical seasonal influenza in adults is typified by a 4- to 5-day period of sudden-onset fever, chills, upper respiratory tract symptoms, headache, muscle pain, and weakness. Rhinitis is relatively uncommon, and diarrhea is more common with influenza than with most rhinovirus upper respiratory tract infections. Severe complications and death can occur, especially in infants, the elderly, and individuals with chronic medical conditions. Among the most severe complications are primary influenza pneumonia and secondary bacterial infection leading to respiratory failure.^{14,15} Influenza can also cause central nervous system, cardiac, skeletal muscle, kidney, and hepatic complications.^{5,15} Underlying pulmonary disease is a frequent risk factor, occurring in 18% of patients, most commonly asthma (7%),

followed by neurologic disease (12%) and hematologic or oncologic (9.9%) and cardiac conditions (4.6%).¹⁶ However, approximately half of those hospitalized (rates ranging from 1 to 5/1000) for influenza are otherwise healthy.¹⁴⁻¹⁶

In the absence of a pandemic, 11% to 19% of patients hospitalized with laboratory-confirmed influenza require treatment in the intensive care unit (ICU).¹⁵ The mean duration of mechanical ventilation is approximately 5 days; the sickest patients require treatment with advanced techniques for hypoxemia, such as high-frequency oscillatory ventilation (HFOV), extracorporeal membrane oxygenation (ECMO), prone positioning, and nitric oxide. These difficult-to-oxygenate patients have increased length of ICU stay and increased mortality.^{14,16,17}

An estimated 50 to 100 million people died during the 1918 pandemic. Death resulted from secondary bronchopneumonia, influenza-related lung disease with associated hypoxemia, and cardiac collapse.^{18,19} During the 1918 pandemic, there was unexplained increased influenza mortality in persons who were 20 to 40 years of age. This mortality increase may have been due to limited native immunity and/or a vigorous immune response directed against the virus in healthy young persons.¹⁸ The high mortality rate observed in the 1918 pandemic would certainly be reduced today as a result of better oxygen delivery, availability of ICUs, vaccines, antibacterial agents, and antiviral medications. However, the impact on hospital care and costs would be dramatic and necessitate extensive critical care management in modern ICUs that have a limited surge capacity to meet the sudden demand for critical care during a severe pandemic. Sophisticated ICU care is often out of reach to patients in many developing countries today, and case-fatality rates in these countries would still remain very high.²⁰

INFLUENZA A 2009 H1N1-RELATED EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Starting March 2009, a novel strain of a human-adapted influenza virus, influenza A (H1N1)pdm09 spread from an initial large outbreak in Mexico to virtually all countries worldwide. By September 27, 2009, there were over 340,000 cases with 4100 deaths worldwide.^{7,21} The World Health Organization issued the first phase 6 pandemic alert of the century, anticipating substantial influenza transmission and related disease. From June to September 2009, there were dramatic spikes in H1N1-related disease in Australia, New Zealand, and South America that breached the capacity for ICU care in some regions.²² Despite blunting of the North American spread of the pandemic by widespread deployment of an effective, inactivated, monovalent vaccine program,²³ modeling suggests as many as 61 million American cases, 274,000 hospitalizations, and approximately 12,500 deaths between April 2009 and April 2010.²⁴ Influenza A (H1N1)pdm09 remained the predominant isolate for several years after the initial pandemic event.

The events that transpired in Canada were illustrative of the influenza situation in much of the Northern Hemisphere in 2009. Among 168 critically ill Canadian patients with influenza A 2009 H1N1, with a mean age of 32 years, there was a possible predilection for more severe disease in women (67% of patients).²⁵ Pregnant women, in particular, suffered from a disproportionately high level of influenza disease severity.²⁵⁻²⁷ Nosocomial transmission was the mechanism of acquisition in approximately 10% of patients. Hospital-acquired transmission to healthcare workers occurred early in the outbreak, but healthcare-related infection occurred at a low incidence rate once the pandemic was recognized and appropriate infection-control safeguards were instituted. One or more comorbidities were observed in nearly all patients; most commonly, these were chronic lung disease such as asthma, chronic obstructive pulmonary disease, bronchopulmonary dysplasia (41%), obesity (33%, mean body mass index of 34.6 kg/m²), hypertension (24%), history of smoking (23%),

TABLE 130-2

Prognostic Indicators and Risk Factors for Severe Influenza Complications

| RISK FACTORS AND COMORBIDITIES | COMMENTS |
|---|---|
| Age <5 years | Children <2 years and those with chronic cardiopulmonary disease at greatest risk |
| Age >65 years | Poor vaccine response, poor host response to influenza infection |
| Chronic cardiopulmonary diseases | COPD, asthma, congestive heart failure |
| Metabolic disease and chronic liver disease | Diabetes mellitus and cirrhosis increase the risk of influenza complications |
| Chronic neurologic illness | Neurocognitive and neuromuscular diseases associated with increased complications |
| Pregnancy | Particularly women in the third trimester |
| Obesity | BMI >35 kg/m ² increased the risk of influenza complications in the 2009 outbreak |
| Hemoglobinopathy | Sickle cell disease patients at increased risk |
| Immunosuppression | Glucocorticoids, chemotherapy, HIV transplant recipients at increased risk |
| Children receiving salicylates | Increased risk of Reye syndrome |
| Aboriginal populations, poverty, poor access to healthcare services | Delayed treatment associated with increased risk of influenza complications |
| Secondary bacterial pneumonia | Bacterial pneumonia associated with longer ICU and hospital stays with more nosocomial complications and a greater mortality rate |

and diabetes (21%). Similar clinical findings and predisposing illnesses were reported in other regions of the world during the 2009 outbreak.^{21,22,28,29} Serious comorbid illness was observed in only 30% of patients. Notably, aboriginal Canadians have thus far been over-represented (26% of patients). A summary of clinical risk factors and comorbidities associated with severe influenza complications is found in Table 130-2.

The most common specific symptoms with influenza A 2009 H1N1 have included fever and respiratory symptoms in more than 90% of patients, with weakness and myalgias being less common. Several severe clinical syndromes associated with influenza A 2009 H1N1 infection may be seen, including:

- Rapidly progressive diffuse pneumonitis associated with severe, refractory hypoxemia in relatively healthy teens or adults and immunocompromised patients
- Decompensation of chronic underlying disease in patients with serious comorbidities including congestive heart failure, chronic renal failure, end-stage liver disease, poorly controlled diabetes, or immunocompromise
- Acute and prolonged exacerbation of chronic obstructive pulmonary disease and asthma in those with preexisting disease
- Bacterial pneumonia, frequently with gram-positive pathogens including *Streptococcus pneumoniae*, *Staphylococcus aureus*, and group A streptococci and superinfection on a background of mild or severe influenza A 2009 H1N1 infection
- Bronchiolitis and croup in infants and young children, who frequently require hospitalization but not ICU care

The typical clinical syndrome requiring ICU care among all age groups appeared to be a diffuse bilateral four-quadrant pneumonitis, which was often rapidly progressive. This process accounted for over 80% of ICU admissions in Canada and elsewhere and often

necessitated advanced ventilatory/oxygenation modalities including HFOV, inhaled nitric oxide, and/or ECMO therapy.^{25,30-33}

Patients who subsequently developed critical illness generally presented to the hospital within 4 days of symptom onset and required ICU admission within 1 day of hospital presentation for bilateral pulmonary infiltrates and hypoxic respiratory failure. The mean Acute Physiology and Chronic Health Evaluation II score was 20. Notable laboratory findings have included elevated creatine kinase levels and normal white blood cell counts.^{21,25,34} Concomitant presenting conditions included possible bacterial pneumonia (32.1%), hypotension requiring vasopressors (13.7%), and asthma or chronic obstructive pulmonary disease exacerbation (13.7%).

Over 80% of patients with H1N1-related acute lung injury (ALI) received mechanical ventilation; very few patients were successfully managed with noninvasive ventilation strategies alone. Oxygenation support included high concentrations of inspired oxygen (mean admission Pao₂/Fio₂, 147 mm Hg), positive end-expiratory pressure (PEEP), frequent use of HFOV (12%), nitric oxide (14%), neuromuscular blockade (30%), prone ventilation (5%), and occasionally, ECMO (7%). Medical therapies included NA inhibitors (90.5%), antibacterial agents (98.8%), and, despite uncertain efficacy, corticosteroids (50.6%).²⁵

Secondary bacterial pneumonia following ICU admission was found in 24% of cases, most commonly due to *S. aureus* and *S. pneumoniae*.^{25,35,36} The frequency of secondary bacterial infection was difficult to accurately determine owing to the widespread use of empiric antibacterial therapy in influenza patients with rapidly progressive respiratory failure. Overall mortality among critically ill patients at 90 days was 17.3% (similar to that reported in Australia).²² The median duration of ventilation was 12 days. The most common cause of death was severe acute respiratory distress syndrome (ARDS) and hypoxemia and complications thereof, secondary infection, sepsis, or multiorgan dysfunction syndrome. Characteristic radiographic changes of severe primary influenza pneumonia are shown in Figure 130-1, A and B.

Lung pathology in fatally infected patients who underwent autopsy revealed a diffuse alveolar filling process, often with early hyaline membrane formation that was sometimes accompanied by focal areas of hemorrhage.³⁷ The alveolar lining was usually thickened, with evidence of lymphocytic infiltrates and early organization with fibrosis. A typical lung tissue section of a patient with fatal influenza pneumonia is seen in Figure 130-2. The lung tissue in deaths occurring early in the presentation of influenza pneumonia often revealed diffuse immunohistochemical evidence of viral infection and intraalveolar hemorrhage.

In children, the median age of hospitalized patients was 5.0 years (range, 1 month to 17 years); 54.4% were females, and the mean PRISM III score was 9.^{14-16,25} One or more chronic comorbid illnesses were observed in 70.2% of patients: lung disease (44%), neurologic diseases (19%), immunosuppression or immunodeficiency (16%), history of prematurity (9%), and congenital heart disease (7%). Mechanical ventilation was used in 68% of children admitted to the ICU, and the median duration of ventilation was 6 days (range, 0-67 days).

CLINICAL AND LABORATORY DIAGNOSIS

Significant difficulties with definitive virologic diagnosis existed in the early phase of the 2009 influenza outbreak. Fever and upper respiratory symptoms were present in almost all patients who progressed to critical illness. However, shortness of breath, a symptom atypical of uncomplicated influenza virus infection, is suggestive of severe disease. Other clinical signs noted in patients with severe disease include hemoptysis, frothy pink sputum, and purulent sputum with diffuse lung crackles. Percutaneous oximetric assessment of oxygenation or arterial blood gas evaluation of Po₂ should be performed when assessing a patient with suspected severe influenza. The presence of relative hypoxia should trigger further assessment including a chest radiograph.

FIGURE 130-1 ■ **A**, Chest radiograph of a 70-year-old male with B-cell lymphoma and hypogammaglobulinemia, with primary influenza pneumonia at the time of ICU admission. Note Port-a-Cath in right anterior chest wall and diffuse pulmonary infiltrates, most prominently seen in both lower lung fields. **B**, Chest radiograph of same patient 3 days later; note diffuse alveolar filling process associated with profound hypoxemia. The patient expired despite oseltamivir and ventilatory support, with severe hypotension and acute kidney injury.

FIGURE 130-2 ■ Lung pathology of fatal case of primary influenza pneumonia in a previously healthy 20-year-old woman. Note diffuse alveolar filling, squamous metaplasia, lymphocytic infiltrates, focal hemorrhage, loss of ventilatable lung tissue. (Figure courtesy David Horn, MD.)

Laboratory findings typically found at presentation with severe disease include normal or low-normal leukocyte counts and elevated creatine kinase levels^{22,25,29} (Fig. 130-3).

Early laboratory diagnosis of influenza infection is greatly facilitated by the use of reverse transcriptase-polymerase chain reaction (RT-PCR).³⁸ This assay should be employed when available when evaluating a patient with suspected severe influenza. Immunofluorescent techniques, enzyme-linked immunoassays, and other rapid diagnostic tests of clinical specimens often lack diagnostic sensitivity.³⁸⁻⁴² Viral cultures require up to 1 week for processing. Although RT-PCR is the preferred definitive diagnostic technique and has very high sensitivity, the adequacy of the clinical specimen is essential. Standard nasopharyngeal swab samples are adequate but can be falsely negative. RT-PCR of

nasopharyngeal samples should be repeated in 48 to 72 hours if diagnostic suspicion remains. Paired nasopharyngeal and tracheal aspirates are useful for RT-PCR in intubated patients and may increase the diagnostic yield in critically ill patients.^{43,44}

SUPPORTIVE CARE

Almost all patients with severe infection in the ICU setting will have deficits in oxygenation and subsequently require ventilatory support.^{22,25,45} Shock and renal failure can occur during therapy as a consequence of efforts to optimize oxygenation through diuresis coupled with high intrathoracic pressures and limited venous return.^{25,29} Other important, but less frequently seen, disorders at presentation may include encephalitis (with or without obtundation or seizure activity), cardiac injury (myocarditis, pericarditis, or conduction defects), and rhabdomyolysis.¹⁷

Most critically ill patients with severe influenza will manifest evidence of ARDS; supportive care for severe hypoxemia with diffuse pulmonary disease and supplemental oxygenation and ventilation assistance are required.²⁵ During pandemics, patients are often relatively young compared with the age of patients in nonpandemic years, and much greater numbers can be expected to be in need of ventilatory support than during a usual flu season.^{18,22,25,30,31}

Primary influenza pneumonia is unusual in that patients often display a relative insensitivity to usual measures of oxygenation assistance with PEEP. Controlled ventilation with attention to a lung-protective strategy,⁴⁶ in combination with appropriate sedation and judicious use of neuromuscular blockade, is appropriate. Avoidance of volume overload (and judicious diuresis) may also be associated with reduced duration of ventilation and length of stay in the ICU for most patients with ALI and ARDS, and this strategy should be attempted for patients with influenza.^{31,47} Other ventilation measures (despite unproven benefit in other forms of ARDS) that might improve oxygenation for individual patients include prone positioning and inhaled nitric oxide.⁴⁸⁻⁵⁰ Unfortunately, HFOV failed as a rescue therapy for patients with severe ARDS in a recent randomized controlled trial,^{50,51} suggesting the probability of lack of utility in patients with influenza-related refractory hypoxemia. ECMO remains

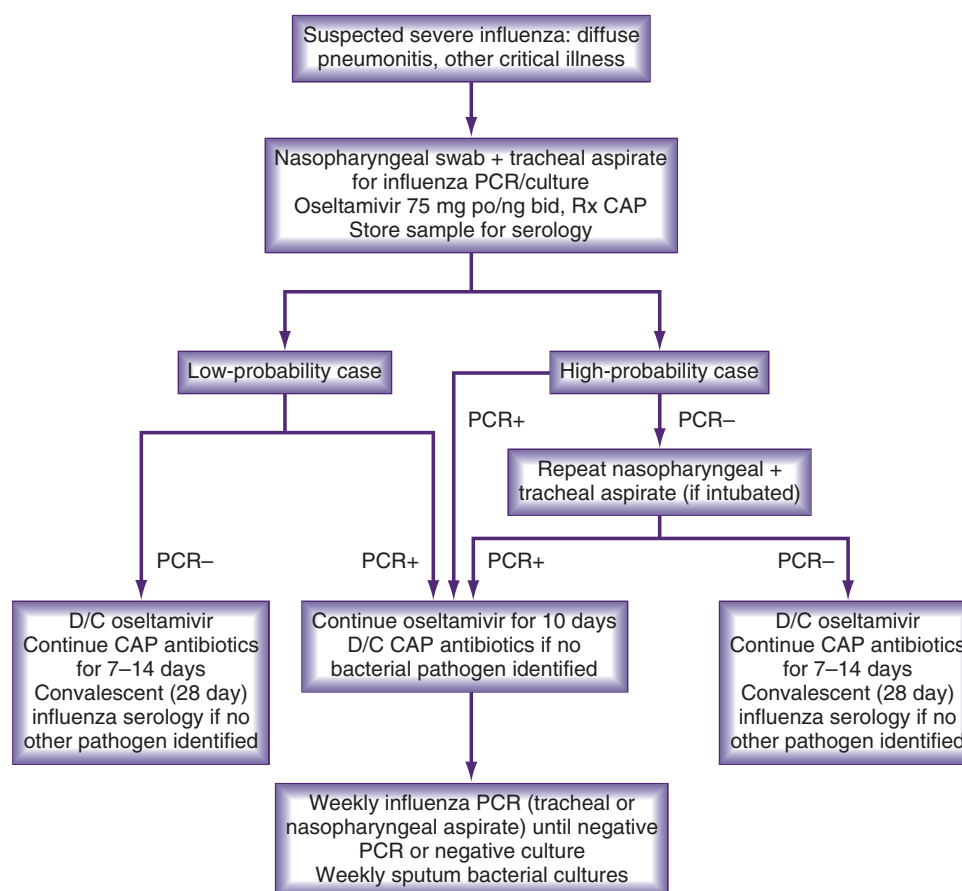

FIGURE 130-3 ■ Suggested algorithm in the workup and management of suspected severe influenza pneumonia in the critical care unit.

a controversial, albeit better supported, option to manage severe respiratory failure in influenza-associated ALI in adults.^{30-33,52} HFOV and ECMO might be considered as salvage therapy in centers familiar with these modalities in selected critically ill patients where other options do not exist.

■ ANTIVIRAL THERAPY

In severely ill patients with suspected influenza, early initiation of antiviral therapy is predicated on clinical presenting features and epidemiologic data. Therapy in such cases must not be delayed pending laboratory confirmation.^{22,25,53,54} Various influenza strains are circulating throughout the world, and susceptibility to currently available antiviral agents is isolate- and strain-specific. The 2009 H1N1 swine influenza variant was resistant to amantadine but sensitive to NA inhibitors including oseltamivir and zanamivir.⁵⁴ Rare oseltamivir-resistant strains were isolated during the 2009 H1N1 influenza A pandemic and remain very uncommon (1.2% frequency among U.S. influenza A(H1N1)pdm09 isolates to during the 2013-2014 season).^{55,56} In contrast, the seasonal H1N1 influenza A strains that predominated before the 2009 season and which persist currently at lower rates to date are often resistant to oseltamivir, yet many remain susceptible to zanamivir.⁵⁶⁻⁵⁸ At this time, only an oral form of oseltamivir and an inhaled form of zanamivir are available for routine use. Intravenous peramivir remains an option in severely ill patients.

Initiation of antiviral therapy within 48 hours of the onset of symptoms of seasonal influenza is associated with a 1-day or greater reduction in the duration of symptoms in ambulatory patients.^{56,59}

Oseltamivir therapy may reduce the risk of secondary bacterial superinfection.⁶⁰ Early therapy of severe influenza A 2009 H1N1 infections requiring ICU support with NA inhibitors appears to contribute to improved outcomes.^{53,54,61-63}

Fewer data are available to guide the optimal dose or duration of therapy for antiviral agents. Severe influenza infections, including those caused by the 2009 H1N1 strain, can represent a systemic infection in addition to a pulmonary infection,⁶⁴ favoring the use of a systemic rather than an inhaled antiviral agent. Despite concerns over inadequate gastrointestinal absorption of oseltamivir among critically ill patients, published studies indicate comparable blood levels in critically ill influenza patients in the ICU with those in normal volunteers.^{65,66} Available evidence suggests that an oseltamivir dose of 75 mg twice daily is adequate. While double or triple dose therapy is well tolerated, no study has suggested improved clinical response or survival in patients treated with these regimens^{53,67}; the only potential advantage appears to be accelerated viral clearance in one randomized, double-blinded, controlled study.⁶⁸

Viral shedding can be prolonged in hospitalized patients with seasonal or pandemic influenza. Among patients with pandemic influenza viral pneumonia (infiltrates and positive tracheal aspirate PCR), the median days for clearance while on oseltamivir therapy was 11.⁴³ NA-inhibitor therapy for longer than 5 days has been used in outbreak situations and in immunocompromised patients known to shed the virus for prolonged periods. The current World Health Organization (WHO) recommendations suggest continued antiviral therapy for critically ill patients with influenza pneumonia until adequate clinical response or infection resolution, but formal studies on optimal duration in this context are lacking.⁷⁰ The intravenous

NA inhibitor peramivir is now available in many countries. The recommended dose in adults is 600 mg of peramivir given intravenously once daily for 5 days.⁷¹

ADJUNCTIVE PHARMACOLOGIC THERAPY

Several potential adjunctive immunomodulatory or antiviral therapies for the treatment of severe influenza exist. Convalescent serum/plasma or hyperimmune globulin derived from patients who have recovered from influenza has been used for many decades. A series of studies were performed using convalescent plasma/serum during the 1918 pandemic; a recent meta-analysis showed that early, but not late, administration of such products may be associated with a significant survival benefit.⁷² Other case series suggest that similar therapy is of use in severe influenza A/H5N1 infection.^{73,74}

High-dose corticosteroid therapy has been advocated for a variety of infectious and inflammatory conditions.⁷⁵ The uncertain benefits and known risks of corticosteroids in the presence of ongoing infection warrant extreme caution before employing this strategy in primary influenza pneumonia. Although no randomized studies have been performed, retrospective analyses suggest prolongation of viral shedding, more frequent superinfections, and increased mortality.⁷⁶⁻⁷⁸

SECONDARY BACTERIAL PNEUMONIA

A majority of deaths from the 1918 influenza pandemic were the result of secondary bacterial infection.^{18,19} Similarly, a substantial number of deaths from the 1957 and 1968 pandemics were caused by bacterial co- or superinfection. The common pathogens in all series have been *S. pneumoniae*, group A streptococci, *S. aureus*, and *Haemophilus influenzae*. Given the frequency of secondary bacterial infection, clinicians should have a low threshold for considering antibacterial agents against these commonly observed pathogens.

Secondary bacterial pneumonia as a complication of viral pneumonia takes two forms: mixed viral/bacterial pneumonia and postinfluenza pneumonia during the convalescent phase of influenza. Postinfluenza pneumonia is generally attributable to damaged airways and poor mucociliary clearance mechanisms following severe influenza pneumonia.¹⁸ The early mixed form of bacterial pneumonia during ongoing viral replication in the airways is more complex, with possible synergism between the bacterial and viral pathogens. Apoptosis of pneumocytes is induced by the viral PB1-F2 protein that facilitates pneumococcal growth in the lung tissue.⁷⁹ Pneumococci bind to epithelial surfaces more readily if sialic acids have been cleaved by NA.⁸⁰ Viral NA from the influenza virus has been found to promote pneumococcal adhesion in lung tissues and increase lethality in experimental pneumococcal pneumonia.⁸¹ The early institution of effective antiviral agents with NA inhibitors might serve to decrease virus replication and decrease the risk of secondary pneumonia.⁶⁰

INFECTION CONTROL IN THE INTENSIVE CARE UNIT

Patients with suspected influenza should be managed using droplet precautions by healthcare professionals who should wear a standard surgical tie mask. There are different recommendations as to which face mask is optimal and whether N95 masks or similar personal respirators might be preferable to surgical tie masks. A recent study found limited to no additional protection of N95 masks in comparison to surgical masks, yet many still advocate their use during cough-inducing procedures when treating patients with influenza.⁸² Vaccines, when available against circulating strains of influenza, should be mandatory for all healthcare workers, unless specific contraindications exist. Healthcare workers should also consider appropriate gloves when they are likely to have contact with body fluids or touch contaminated surfaces, and they should wear gowns during procedures and patient-care activities where clothing might become contaminated. Protective eyewear is recommended when providing direct care in close proximity to the patient.⁸³ Patients with suspected influenza should be in single-patient rooms, if available, during the initial phase of hospital admission. If clinical demand exceeds the availability of single rooms, then cohorting patients with influenza into common rooms may be necessary. Influenza patients who must be transported outside a room should wear a mask if tolerated or, when necessary, an oxygen delivery system that limits the spread of aerosols.

With respect to infection prevention and control related to mode of ventilatory assistance, there is circumstantial evidence from the severe acute respiratory syndrome epidemic that noninvasive ventilation and HFOV may promote excess aerosolization of viral-laden particles and place surrounding patients and staff at risk. Limited evidence suggests that the process of endotracheal intubation, especially in an uncontrolled setting, is associated with an increased risk of acquiring infection; however, this risk is mitigated if adequate personal protective equipment is worn.^{84,85} HFOV circuits should be equipped with microbial filters and a scavenger system to the exhalation port to limit aerosol generation.

GLOBAL CRITICAL CARE COLLABORATION

The WHO does a superb job monitoring for outbreaks and antigenic shift and drift in influenza viruses in animals and human populations, but they are not equipped to perform ICU-based, international, clinical trials should a pandemic outbreak occur. A working group composed of members from the international critical care community has been formed, known as the *International Forum for Acute Care Trialists* (InFACT), to aid with global collaborative research in critical care during pandemics.⁸⁶ The impact of the InFACT initiative or similar cooperative groups will only be determined over time, but such organizations will attempt to more efficiently and more inclusively improve the care of critically ill patients in future international epidemics.

KEY POINTS

1. Influenza has exacted an enormous cost in human lives since antiquity and continues to cause annual epidemics and excess deaths to the present day.
2. Influenza A is responsible for periodic pandemics when influenza viruses from wild and domesticated bird species reassort with human-adapted viruses to generate new, hybrid viruses to which the entire human population is susceptible.
3. Specific antiinfluenza agents are available, particularly the neuraminidase inhibitors oseltamivir and zanamivir, but point mutations at the target site are increasingly common and induce resistance.
4. Secondary bacterial pneumonia following primary influenza pneumonia are common and are usually caused by pneumococci or *Staphylococcus aureus*.

Continued

KEY POINTS—cont'd

5. Supportive care and ventilatory assistance if needed can be lifesaving in severe influenza and often require prolonged ICU care for full recovery.
6. Until improved vaccines with long-term, cross-protective immunity become available, annual influenza vaccines remain mandatory for all healthcare workers to protect them and prevent nosocomial outbreaks caused by infected healthcare workers.
7. Droplet precautions and ventilatory equipment airway filters need to be followed when caring for influenza patients in critical care units, until they are no longer shedding viruses in respiratory secretions (usually 5-7 days but can be longer in critically ill and immunocompromised patients).

ANNOTATED REFERENCES

Molinari NA, Ortega-Sanchez IR, Messonnier ML, Thompson WW, Wortley PM, Weintraub E, et al. The annual impact of seasonal influenza in the US: measuring disease burden and costs. *Vaccine* 2007;25:5086–5096.

This paper presents a careful analysis of the direct costs to society in medical expenditures for the care of patients with influenza in one season throughout the United States. The costs are exceedingly high and argue strongly in favor of widespread use of annual influenza vaccines as a cost-savings measure.

Kumar A, Zyarychanski R, Pinto R, Cook DJ, Marshall J, Lacroix J, et al. Critically ill patients with 2009 influenza A (H1N1) infection in Canada. *JAMA* 2009;302:1872–1879.

This report provides a detailed and valuable review of the impact of influenza upon critical care services and the relative values of various support measures in managing critically ill patients during an outbreak of pandemic influenza A (H1N1) in 2009.

Novel Swine-Origin Influenza A (H1N1) Virus Investigation Team. Emergence of a novel swine-origin influenza A (H1N1) virus in humans. *N Eng J Med* 2009;360:2605–2615.

This paper traces the fundamental virology, evolution, and epidemic behavior of the novel influenza A strain that caused a worldwide pandemic in 2009.

Moscona A. Global transmission of oseltamivir-resistant influenza. *N Engl J Med* 2009;360:953–956.

This report defines the molecular mechanisms responsible for development of resistance to the neuraminidase-inhibitor antiviral agents against influenza and explains why this is a major problem for oseltamivir rather than for a related antiviral agent, zanamivir.

Garten RJ, Davis CT, Russell CA, Shu B, Lindstrom S, Balish A, et al. Antigenic and genetic characteristics of swine-origin 2009 A(H1N1) influenza viruses circulating in humans. *Science* 2009;325:197–201.

This paper provides the molecular details about the novel swine-origin quadruple reassorted influenza A H1N1 pandemic strain of 2009 and how it escapes immune clearance preexisting antibodies against currently circulating H1N1 strains. The virus possesses rapid human-to-human transmission potential but lacks many important virulence properties of many previous pandemic influenza viruses. These features explain its high transmissibility but rather low mortality rate.

Gamblin SJ, Haire LF, Russell RJ, Stevens DJ, Xiao B, Ha Y, et al. The structure and receptor binding properties of the 1918 influenza hemagglutinin. *Science* 2004;303:1838–1842.

This structural immunology paper analyzes the unique ability of the 1918 hemagglutinin to bind equally well to the α 2,3-linked sialic acid-galactose moieties covering avian epithelial surfaces and to the α 2,6-linked sialic acids typically found on human epithelial surface glycopeptides.

Harper SA, Bradley JS, Englund JA, File TM, Gravenstein S, Hayden F, et al. Seasonal influenza in adults and children—diagnosis, treatment, chemoprophylaxis and institutional outbreak management: clinical practice guidelines of the Infectious Disease Society of America. *Clin Infect Dis* 2009;48:1003–1032.

This paper provides a useful review of the current existing evidence in support of a variety of diagnostic, therapeutic, and infection-control measures that are instituted when managing patients with influenza. This up-to-date guideline is a practical guide to optimal care of influenza in individual patients and in institutions during an outbreak.

Many changes have occurred in the overall management and prognosis of patients with human immunodeficiency virus (HIV). The development of combination antiretroviral therapy (ART), in concert with chemoprophylaxis for opportunistic infections, has led to dramatic improvements in the morbidity and mortality of patients infected with HIV.^{1,2} However, those not known to be HIV-infected, those without access to medications, or those who are not responding to antiretroviral therapy may still present with AIDS-associated opportunistic infections and neoplasms.³

In this chapter, we discuss recent trends in the epidemiology and survival of HIV-infected patients admitted to an intensive care unit (ICU). Because *Pneumocystis jirovecii* pneumonia (PCP) continues to be an important cause of respiratory failure in HIV-infected patients and carries a high ICU mortality rate, we will also discuss diagnosis and treatment of PCP. Finally, we will examine problems unique to the ICU care of HIV-infected patients, particularly those related to combination ART.

INTENSIVE CARE TRENDS AMONG HIV-INFECTED PATIENTS

Epidemiology

Both the epidemiology of ICU admissions and views of the utility of ICU care for HIV-infected patients have undergone several shifts during the course of the AIDS epidemic. In the beginning of the epidemic, most patients with HIV infection admitted to the ICU had PCP, survival was poor, and ICU admission was often considered futile.⁴ Over the course of the epidemic, bacterial pneumonia, sepsis, and non-HIV-associated diagnoses have become increasingly common.⁴⁻⁷ With the widespread availability of combination ART, there have been continued changes in epidemiology and ICU mortality, and ICU care is again indicated for most patients. Unfortunately, with reports of antiretroviral resistance and transmission of multidrug-resistant HIV, ICU trends may shift again, with an increase in opportunistic infections and poor outcomes.⁸⁻¹⁰

The most extensive series documenting ICU epidemiology has come from San Francisco General Hospital, where researchers have tracked the trends in ICU diagnoses, admissions, and survival throughout the different eras of the AIDS epidemic. In the initial years (era I: 1981-1985), overall hospital mortality for those admitted to an ICU was 69%, and median survival was only 7 months.⁴ Owing to administration of corticosteroids in PCP and the initial development of ART, ICU mortality decreased over the next 10 years to 36.9%, a significant improvement from era I.⁴⁻⁷

Combination ART (era V: 1996-1999) brought about the most significant changes in mortality and admission rates.¹¹ The number of ICU admissions at San Francisco General Hospital decreased significantly from an average of 111 per year in era IV to 88.5 per year, and the survival rate increased to 71%. Respiratory failure was still the most common cause of ICU admission (40.7% of diagnoses), and PCP accounted for 10.7% of admissions compared with 17.6% in the preceding era. Shifts in ICU patient demographics reflected national trends in the HIV epidemic; whereas the majority of patients in previous eras had been white homosexual men, now African-Americans

accounted for 44.6% of ICU admissions, and women and intravenous (IV) drug users were also more commonly admitted.^{7,11} During era VI (2000-2004), as survival rates steadily increased, PCP was the most common cause of respiratory failure in patients not on ART, while obstructive airways disease was the most common among patients on ART.¹²

Exact mortality and admission rates are different in different centers, but overall trends of decreasing mortality and changes in the spectrum of diagnoses related to HIV are similar.^{13,14} In a 12-year, multicenter study of 6373 HIV-infected patients admitted to the ICU during the ART era, overall mortality decreased from 18.3% in the years 1999-2001 to 16.2% in 2008-2010.¹⁵

In most series, respiratory failure remains the leading cause of ICU admission in HIV-infected patients, although the percentage of respiratory admissions has declined. In the ART era, bacterial pneumonia has become more common, although PCP still accounts for many cases of respiratory failure.¹²⁻¹⁶ ICU admissions for severe sepsis have increased and are often associated with respiratory failure.^{16,17} HIV-infected patients with bacterial pneumonia are more likely to become bacteremic, and mortality approaches 68% in this setting.¹⁸

Non-AIDS-related diagnoses such as myocardial infarction, airway obstruction, and trauma are becoming more common, as are ART-associated diagnoses.^{16,19} In addition to respiratory failure, other comorbid conditions associated with HIV infection may be seen on admission to the ICU. These include cardiac disease, end-stage liver disease, and HIV-related renal disease. Combination ART has been associated with metabolic syndrome, dyslipidemias, and an increased risk of myocardial infarction.²⁰⁻²² End-stage liver disease due to viral hepatitis and HIV co-infection is a significant nonrespiratory problem seen in HIV-infected patients admitted to the ICU. Due to similar routes of infection, chronic hepatitis B virus has been reported in 10% and chronic hepatitis C virus (HCV) in 25% of HIV-infected individuals.²³ In the HIV Outpatient Study, the prevalence of HCV co-infection has decreased over time, from 36.7% in 1996 to 19.7% in 2007; however, HCV co-infection is associated with a higher ICU mortality than with HIV alone.^{24,25} HIV is a known risk factor for the accelerated progression of HCV to cirrhosis, and in addition to hepatotoxicity from co-infection, many antiretrovirals also elevate transaminase levels.^{26,27} Finally, end-stage renal disease secondary to HIV is a common complication. Despite the decreased incidence with the development of combination ART, it remains a significant problem, especially in HIV-infected African-Americans, who are at higher risk of developing HIV-associated nephropathy with progression to end-stage renal disease.²⁸⁻³¹

Prognostic Factors

Several key factors continue to impact mortality, and these factors seem not to have changed over the years. Mechanical ventilation, diagnosis of PCP, and vasopressor use have been associated with increased mortality.^{7,11,13,17} Conversely, admission for a non-AIDS-associated diagnosis, an albumin level greater than 2.6 g/dL, an Acute Physiology and Chronic Health Evaluation (APACHE) II score less than 13, and no need for mechanical ventilation were all associated with increased survival to hospital discharge.^{11,12}

INTENSIVE CARE TRENDS IN PNEUMOCYSTIS PNEUMONIA

Because PCP has historically been the most common cause of respiratory failure in patients with AIDS, more is known about ICU outcomes of those with PCP than for any other HIV-infected group. In the 1980s, patients with HIV and PCP who required intensive care had a mortality rate as high as 81%, rising to 87% if they required mechanical ventilation.⁴ Mortality due to PCP decreased to approximately 60% with the introduction of adjunctive corticosteroids in the mid-1980s and has continued to decline in the era of combination ART.^{5,32-34}

Despite improvement in PCP survival, a diagnosis of PCP remains a risk factor for overall mortality.^{12,35} In a study of HIV-infected individuals from 1998 to 2010, in-hospital mortality remained unchanged at 10.9% of HIV-infected patients admitted with PCP, despite advances in ART over those years.³⁶

Diagnosis and Treatment of *Pneumocystis Pneumonia*

Clinical Presentation

PCP most commonly occurs in patients with CD4 cell counts below 200 cells/ μ L, and the risk of PCP increases exponentially as the CD4 cell count further decreases below that level.^{37,38} Common symptoms and signs include fever, tachypnea, dyspnea with a nonproductive cough, and a chest examination that is normal or has a few dry rales.^{39,40} In the HIV-infected patient, symptoms have generally been present for days to weeks before the diagnosis is made. Approximately two-thirds of patients admitted to the ICU with PCP are unaware they are infected with HIV, so clinicians must remember to include PCP in their differential diagnosis of respiratory failure, even in individuals not known to have HIV.^{34,41}

Severe PCP is often similar in presentation and pathogenesis to acute respiratory distress syndrome (ARDS). The organism appears to cause a widespread capillary leak, and the chest radiograph usually resembles that in ARDS, with diffuse bilateral interstitial infiltrates. Less commonly, PCP results in focal airspace consolidation. Infiltrates are occasionally unilateral or asymmetric, and the pattern (interstitial and nodular) is more suggestive of the diagnosis than distribution of the abnormalities. However, about 10% to 15% of patients proven to have PCP initially have normal chest radiographs.⁴²⁻⁴⁴

Diagnosis

Although PCP may have a typical clinical and radiographic presentation, definitive diagnosis is encouraged, particularly in those who are critically ill. Many respiratory diseases in HIV have overlapping presentations, and prompt initiation of appropriate therapy is important to prevent clinical deterioration and avoid unnecessary drug side effects. The diagnosis of PCP is made by identifying the organism in the pulmonary secretions of a patient with a compatible clinical presentation. PCP may be diagnosed by examination of induced sputum,

which has a sensitivity of 79% and a negative predictive value of 61% in experienced hands.⁴⁵

When the sputum examination is negative or when it is not possible to obtain induced sputum, bronchoscopy with bronchoalveolar lavage is the procedure of choice, with a sensitivity of over 90% for diagnosis of PCP in an HIV-infected individual and an even greater yield when bilateral sampling is performed.⁴⁶⁻⁴⁸

In recent years, the search for noninvasive biomarkers in the diagnosis of PCP has yielded promising results. Detection of β -D-glucan in the serum has been shown to be both a sensitive and specific indicator of PCP in HIV-infected individuals.^{49,50} Interestingly, serum measurement of β -D-glucan is more sensitive and specific than bronchoalveolar lavage fluid measurement of the marker.⁵⁰ Although studies to date have been retrospective in nature, this biomarker shows promise in the risk stratification of HIV-infected individuals who may have PCP.

Treatment

A summary of treatment regimens in decreasing order of preference is given in Table 131-1. The treatment of choice for moderate to severe PCP is intravenous (IV) trimethoprim-sulfamethoxazole (TMP-SMX) for a total of 21 days.⁴⁰ Approximately 25% of patients will have therapy-limiting toxicity from TMP-SMX (Table 131-1), occurring between days 6 and 10 of treatment.⁵¹⁻⁵³

Intravenous pentamidine isethionate is an effective alternative for therapy in patients who cannot tolerate TMP-SMX or have failed treatment.⁴⁰ Because pentamidine is toxic to the pancreatic islet cells, initial hypoglycemia from a surge of insulin release followed by hyperglycemia from inadequate insulin may be seen, and the patient may progress to chronic diabetes mellitus. Adverse reactions may be seen in as many as 50% of patients treated with pentamidine.

Second-line therapy may be used if first-line therapies prove to be ineffective or have unacceptable side effects. If TMP-SMX has been the first-line agent, IV pentamidine or the combination of IV clindamycin with oral primaquine may be substituted.

The most profound improvement in PCP mortality occurred with the introduction of adjunctive corticosteroids.^{5,32,33} In a meta-analysis of six randomized controlled trials comparing adjunctive corticosteroids to standard care in HIV-infected patients with PCP, risk ratios for overall mortality were 0.54 (95% CI, 0.38-0.79) at 1 month and 0.67 (95% CI, 0.49-0.93) at 3 to 4 months in favor of corticosteroids.⁵⁴ It is recommended that patients with PCP and either a P_{aO_2} on room air of less than 70 mm Hg or an alveolar-arterial oxygen gradient greater than 35 mm Hg receive prednisone within 72 hours of initiating anti-*Pneumocystis* therapy to reduce mortality (Table 131-1).⁴⁰ For those patients unable to take oral medications, IV methylprednisolone may be substituted at 75% of the prednisone dose.⁴⁰

Treatment Failure

Worsening respiratory status with a decrease in arterial oxygenation is common 3 to 5 days after initiation of treatment. This is likely due to

TABLE 131-1 Treatment Regimens for Severe *Pneumocystis Pneumonia* in Decreasing Order of Preference

| AGENT | DOSE | SIDE EFFECTS |
|--|--|---|
| Trimethoprim-sulfamethoxazole | Trimethoprim, 15-20 mg/kg/d, with sulfamethoxazole, 75-100 mg/kg/d IV, divided q 6-8 h | Rash, nausea, bone marrow suppression, hyponatremia, hyperkalemia, nephrotoxicity, transaminitis |
| Pentamidine isethionate | 3-4 mg/kg/d IV | Nausea, hypotension, hypoglycemia or hyperglycemia, pancreatitis, bone marrow suppression, nephrotoxicity |
| Clindamycin-primaquine | Clindamycin, 900 mg IV q 8 h; primaquine, 30 mg PO daily | Nausea, diarrhea, rash, hemolytic anemia, methemoglobinemia, leukopenia |
| ADJUNCTIVE THERAPY | | |
| Prednisone if $P_{aO_2} < 70$ mm Hg or alveolar-arterial gradient > 35 mm Hg | 40 mg PO q 12 h for 5 days, 40 mg PO daily for 5 days, 20 mg PO daily for 11 days | Hyperglycemia, psychosis |

an inflammatory response to dead or dying organisms that may increase capillary permeability and pulmonary edema formation, and it may be inadvertently worsened by administration of excessive IV fluids. Given that patients' conditions may deteriorate and that symptoms may be prolonged, it is difficult to determine when a treatment regimen is failing and should be abandoned for an alternative. *Pneumocystis* has been shown to develop genetic mutations with exposure to sulfa- or sulfone-containing medications such as TMP-SMX and dapsone, although how these mutations impact outcome is still controversial.⁵⁵⁻⁵⁷ In general, treatment should be continued for 4 to 8 days before considering changing to a different agent.⁴⁰ It is also important to investigate alternative diagnoses including opportunistic pathogens, immune reconstitution inflammatory syndrome, and nosocomial organisms. Patients with PCP are also at increased risk of pulmonary edema, which may explain worsening respiratory status with increasing radiographic infiltrates. Repeat bronchoscopy is helpful to diagnose agents other than PCP, but it is not useful in determining whether PCP treatment is failing because *Pneumocystis* may persist in bronchoalveolar lavage fluid for several weeks.⁵⁸

Ventilation of the Patient with PCP

The pathophysiology of severe PCP resembles that of ARDS, and patients with PCP are at high risk for developing barotrauma and pneumothoraces, often heralding a fatal outcome. Low tidal volume ventilation as per the ARDSNet Ventilator Protocol has been shown to be associated with decreased mortality in HIV-infected patients with acute lung injury (OR, 0.76 per 1-mL/kg decrease; 95% CI, 0.58-0.99; $P = 0.043$), and is standard-of-care in HIV-infected patients with acute lung injury from PCP or other causes.^{35,59} Noninvasive positive-pressure ventilation has been found to lower the rate of intubation, decrease the incidence of pneumothorax, and improve ICU survival.⁶⁰

COMBINATION ANTIRETROVIRAL THERAPY AND THE ICU

Lactic Acidosis

The syndrome of severe hepatic steatosis and lactic acidosis in patients receiving ART was first described in the 1990s.^{61,62} The syndrome is most commonly associated with nucleoside reverse transcriptase inhibitors (NRTIs), particularly didanosine and stavudine, and results from the mitochondrial toxicity of these agents.^{63,64} The incidence of hyperlactatemia in patients taking NRTIs has been reported as high as 227 cases per 1000 person-years. Symptomatic lactic acidosis ranges from 1 to 25.2 cases per 1000 patient-years, with mortality as high as 77%.^{65,66} Risk factors for development of hyperlactatemia include older age, drug regimens containing stavudine or combined stavudine-didanosine, concomitant buprenorphine, creatinine clearance under 70 mL/min, and a nadir CD4 cell count less than 250 cells/ μ L.^{67,68} A case-control study identified female sex and obesity as risk factors for stavudine-related lactic acidosis.⁶⁷

Patients often present with abdominal pain, nausea, and vomiting and may have myalgias or peripheral neuropathies. Serum lactate levels are elevated, and hepatic steatosis and transaminitis occur frequently. Often, cessation of the ART results in resolution; however, some patients progress to life-threatening organ failure. An initial lactate level above 9 mmol/L has been associated with a higher risk of death, and some consider a level greater than 5 mmol/L life threatening.^{69,70}

In patients presenting with mild lactic acidosis, the offending agent should be switched to a safer alternative. Lactate levels should be closely monitored after changing the NRTI. For severe lactate acidosis, ART should be discontinued and supportive care administered.²⁷ Although data regarding treatment outcomes are not extensive, treatment with riboflavin, thiamine, and L-carnitine has reversed the toxicity in some case reports.^{27,69-72} One recommended regimen is to administer 50 mg of riboflavin daily with 50 mg/kg of L-carnitine and 100 mg of thiamine until the lactic acidosis resolves. The exact length

of treatment and the lactate level above which treatment is futile are unclear.

Immune Reconstitution

The immune reconstitution inflammatory syndrome (IRIS) leads to paradoxical worsening of an infection shortly after initiation of ART. This syndrome results from improvement in the immune system and a renewed inflammatory response directed against infectious agents.⁷³ Although this syndrome has been reported to occur in diseases such as tuberculosis, cytomegalovirus (CMV), and *Mycobacterium avium* complex, it usually results only in a symptomatic worsening of these conditions.⁷³⁻⁷⁵ A 2010 meta-analysis of 54 cohort studies of patients who developed IRIS found that it occurred in 16.1% of all patients and was associated with a 4.5% mortality, though mortality varied depending on the underlying pathogen and severity of immunodeficiency at the time of ART initiation.⁷⁶ There have been case reports of paradoxical worsening occurring during PCP, with patients experiencing increasing respiratory distress and hypoxemia and some requiring mechanical ventilation.⁷⁷⁻⁷⁹ All patients subsequently recovered, and there seemed to be some benefit from continuing or reintroducing corticosteroids.⁷⁹ Patients admitted to the ICU with a presumed paradoxical worsening of PCP should receive corticosteroids, and appropriate testing should be performed to rule out other infections or respiratory disorders causing clinical worsening.

Administration of Antiretroviral Therapy in the ICU

The question of whether to continue or initiate ART while HIV-infected patients are in the ICU is an unresolved issue in critical care. Traditionally, antiretroviral regimens have been discontinued while patients are in intensive care, and clinicians have been reluctant to initiate ART in this population. Many issues relating to the use of ART exist in the ICU, including possible poor gastric absorption of antiretroviral medications, the potential for drug interactions and side effects, and concern about patient compliance in continuing ART after discharge. There is also concern that initiating ART in a patient with borderline respiratory status might lead to respiratory failure through paradoxical worsening and immune reconstitution.

ART therapy is complicated in the ICU. Only zidovudine is available in an IV form. Other agents are available as liquids and therefore could be administered via a feeding tube (Box 131-1).⁸⁰ If physicians

FUSION INHIBITOR

Enfuvirtide (subcutaneous injection)

choose to administer ART to an ICU patient, they need to be particularly aware of possible side effects including renal toxicity and hepatotoxicity, pancreatitis, and lactic acidosis.²⁷ Many common ICU medications such as benzodiazepines, fluconazole, pentamidine, and amiodarone may have dangerous interactions or altered metabolism when given with antiretrovirals.²⁷ Medications may also affect the serum levels of antiretrovirals, resulting either in toxic or subtherapeutic concentrations and increasing the risk of developing drug resistance.²⁷ Consultation with a specialist familiar with the many antiretroviral regimens is advised.

It is currently unclear whether the mortality benefits of ART administration in ICU patients outweigh the risks and difficulties. In a randomized controlled trial that compared deferring ART or initiating it within 14 days of treatment for an AIDS-related opportunistic infection or serious bacterial infection, early ART resulted in decreased progression of AIDS or death compared to deferred therapy (OR 0.51).⁸¹ In a retrospective cohort study of 278 HIV-infected patients admitted to the ICU in São Paulo from 1996 through 2006, beginning ART during the ICU stay was associated with reduced 6-month mortality, significantly less than patients not on ART while in the ICU (hazard ratio 0.55).⁸² Survival was worse in those who were previously on ART and had it stopped while in intensive care; however, use of ART in the ICU was associated with adverse events in 18% of patients. In patients with PCP admitted to the ICU during the ART era, mortality among patients who did not receive ART was 63%, whereas those patients either receiving ART at time of admission or started on ART in the ICU had a mortality rate of only 25%.⁸³ There have been several reports of improved cumulative survival (i.e., months to years post ICU discharge) among ICU survivors started on ART.^{17,35,84-86} Other studies, however, have not found that starting ART in the ICU improves ICU or in-hospital survival and that it may be associated with a higher incidence of subsequent antiretroviral resistance.^{34,81,87} One study of HIV-infected patients with respiratory failure found a trend toward worse outcome in those receiving ART in the ICU (30% mortality in those on ART vs. 15% in those not on ART).¹³

Given the lack of consensus guidelines for whether and when to initiate combination ART in the ICU, the decision to do so must be made on a case-by-case basis. A useful treatment strategy was described by Huang and colleagues.⁸⁸ In patients who are known to be HIV-infected and are already receiving combination ART, combination ART should be continued if the viral load is undetectable and there are no contraindications to continuing the drugs (e.g., drug toxicities, resistance, IRIS, difficulty in delivery or drug absorption). If the patient has a contraindication to ART, the entire regimen should be held so as not to foster resistance, and an HIV specialist should be consulted. In patients who are known to be HIV-infected but are not on ART or who are diagnosed with HIV on their ICU admission, consideration should be given to starting combination ART if the condition is an AIDS-associated condition, and an HIV specialist should be consulted. If the condition is not AIDS-associated and the CD4 count is greater than 200 cells, ART should probably be deferred until after the patient is discharged from the ICU, unless the ICU course is prolonged. The importance of consultation with an HIV specialist in these ART treatment decisions cannot be overemphasized.

METABOLIC ABNORMALITIES IN THE ICU

Metabolic Complications of Antiretroviral Therapy

Many drugs included in ART regimens have adverse effects on the metabolism of lipids and glucose. Patients treated with these drugs

commonly develop metabolic abnormalities including hyperlipidemia, hypercholesterolemia, glucose intolerance, and diabetes.⁸⁹⁻⁹¹ Conditions such as cardiovascular disease, dyslipidemia, insulin resistance, and osteoporosis have been associated with ART, and protease inhibitors have been specifically implicated in an increased relative risk of myocardial infarction (MI).^{20,21,92,93} In the landmark multicenter prospective study of 23,468 patients, the Data Collection on Adverse Events of Anti-HIV Drugs (DAD) study group reported that combination ART was independently associated with a 26% relative increase in the rate of MI per year of exposure in the first 4 to 6 years of use.²¹ In a follow-up study, the group showed that exposure to protease inhibitors was associated with increased risk of MI, likely related to dyslipidemia.²⁰ Other studies have reported that the NRTIs abacavir and didanosine are also associated with increased risk of cardiovascular disease, though not all studies support this association.^{94,95} A cohort of over 36,000 HIV-infected patients followed from 1993 to 2001 demonstrated no relationship between use of antiretroviral medications and cerebrovascular or cardiovascular events, but follow-up may have been too short to detect an effect.⁹⁶ A recent study of 81,322 veterans showed that when comparing people of similar cardiovascular risk profiles, HIV-infected veterans had a significantly greater risk of acute MI.⁹⁷ In general, HIV-infected patients admitted to the ICU with cardiac disease should be treated the same as the HIV-uninfected population, with interventions including cardiac artery bypass grafting as indicated. Data show that short-term outcome is equivalent, although HIV-infected patients have a higher long-term risk of requiring revascularization and higher risk of death at 1 year post acute MI.^{98,99} As HIV-infected patients live longer due to ART, clinicians can expect to see problems such as cardiac disease more frequently as the HIV-infected population ages.

Adrenal Insufficiency

Adrenal insufficiency (AI) is an important syndrome in the ICU that is more common among HIV-infected patients. The adrenal glands of patients with HIV may be damaged by infections such as CMV, neoplasms such as lymphoma, and drugs such as ketoconazole and rifampin.¹⁰⁰⁻¹⁰² At its most severe, AI can present as refractory hypotension and may lead to death if not recognized. Marik and colleagues studied adrenal function in 28 critically ill HIV-infected patients. In this study, depending on the criteria used, the rate of AI varied from 7% to 75%.¹⁰³ CMV infection was more common among the patients with AI. Clinicians should have a high degree of suspicion for adrenal insufficiency in HIV-infected patients, particularly in those with CMV, and should consider adrenocorticotrophic hormone stimulation testing. Patients with septic shock or early ARDS should be empirically treated for AI according to the Surviving Sepsis Campaign Guidelines for Management of Severe Sepsis and Septic Shock.¹⁰⁴

CONCLUSION

The outlook for ICU patients with HIV has improved dramatically since the beginning of the AIDS epidemic. Physicians caring for HIV-infected patients in the ICU need an understanding of both the HIV-associated and the non-HIV-associated conditions that can affect these patients. Knowledge of antiretroviral therapies and their side effects is also important because these therapies may lead directly to patients' ICU admissions and impact their morbidity and mortality. It is hoped that more information will become available to guide clinicians in the use of ART in the ICU and that survival will continue to improve.

KEY POINTS

1. Non-AIDS-related diagnoses have become more common since the introduction of combination antiretroviral therapy (ART).
2. Mortality from *Pneumocystis pneumonia* (PCP) can still be high, particularly if patients develop a pneumothorax while on mechanical ventilation.
3. Clinicians should have a high suspicion for PCP, because many patients will not be aware that they are HIV-infected before ICU admission.
4. Early bronchoscopy with bronchoalveolar lavage should be performed in patients with pneumonia who do not have a definitive microbiological diagnosis.
5. Trimethoprim-sulfamethoxazole is the treatment of choice for PCP, and corticosteroids should be given to those meeting established criteria.
6. Fatal lactic acidosis can develop as a result of antiretroviral medications. Treatment consists of drug discontinuation and supportive care.
7. Immune reconstitution syndrome after initiating ART can occasionally lead to respiratory failure, particularly in patients with PCP.
8. Administration of ART in the ICU is difficult, may lead to viral resistance, and is associated with many side effects and drug interactions; however, the association of ART with mortality in the ICU remains unclear.

ANNOTATED REFERENCES

- Barbier F, Coquet I, Legriel S, et al. Etiologies and outcome of acute respiratory failure in HIV-infected patients. *Intensive Care Med.* 2009;35:1678-1686.
- A retrospective study of 147 HIV-infected patients admitted to an ICU for acute respiratory failure (ARF) between 1996 and 2006, describing the etiologies of respiratory failure in this cohort. The most common cause of ARF was bacterial pneumonia ($n = 74$), followed by *Pneumocystis jirovecii* pneumonia (PCP; $n = 52$), other opportunistic infections ($n = 19$), and noninfectious pulmonary disease ($n = 33$). Two or more causes were identified in 33 patients. The 43 patients on ART more frequently had bacterial pneumonia and less frequently had opportunistic infections ($P = 0.02$). Noninvasive ventilation was needed in 49 patients and endotracheal intubation in 42. Hospital mortality was 19.7%. Factors independently associated with mortality were mechanical ventilation (OR, 8.48; $P < 0.0001$), vasopressor use (OR, 4.48; $P = 0.03$), time from hospital admission to ICU admission (OR, 1.05 per day; $P = 0.01$), and number of causes (OR, 3.19; $P = 0.02$). HIV-related variables (CD4 count, viral load, and ART) were not associated with mortality.
- Casolino E, Wolff M, Ravaud P, Choquet C, Bruneel F, Regnier B. Impact of HAART advent on admission patterns and survival in HIV-infected patients admitted to an intensive care unit. *AIDS.* 2004;18:1429-1433.
- This prospective observational cohort study of 426 HIV-infected patients admitted to an ICU between 1995 and 1999 examined ICU epidemiology and survival. The incidence of sepsis increased, while AIDS-related admissions decreased. Overall ICU survival was 77%, and cumulative survival rates after ICU discharge were 85.3% and 70.8% after 1 year and 2 years, respectively. While ICU survival was dependent on the non-HIV-associated prognostic indicators (SAPS II score > 40 , Omega score > 75 , and mechanical ventilation), long-term survival was associated with HIV disease stage and availability of combination ART.
- Davis JL, Morris A, Kallet RH, et al. Low tidal volume ventilation is associated with reduced mortality in HIV-infected patients with acute lung injury. *Thorax.* 2008;11:988-993.
- This retrospective cohort study compared ventilator strategies in 148 HIV-infected patients with respiratory failure before and after the introduction of low tidal volume ventilation in 2000. Among all those with acute lung injury, lower tidal volume was associated with decreased mortality (adjusted OR, 0.76 per 1-mL/kg decrease; 95% CI, 0.58-0.99; $P = 0.043$). This study supports the use of a low tidal volume ventilation strategy in HIV-infected patients with acute lung injury and respiratory failure.
- Dickson SJ, Batson S, Copas AJ, Edwards SG, Singer M, Miller RF. Survival of HIV-infected patients in the intensive care unit in the era of highly active antiretroviral therapy. *Thorax.* 2007;62:964-968.
- This retrospective study of 102 HIV-infected patients admitted to the ICU between January 1999 and December 2005 reported an overall ICU and hospital survival of 77% and 68%, respectively. Factors predicting survival to ICU discharge included hemoglobin, CD4 cell count, APACHE II score, and mechanical ventilation. Use of combination ART was not associated with survival. Outcomes for HIV-infected patients were comparable to general medical patients.
- Muller M, Wandel S, Colebunders R, et al. Immune reconstitution inflammatory syndrome in patients starting antiretroviral therapy for HIV infection: a systematic review and meta-analysis. *Lancet Infect Dis.* 2010;10:251-261.
- A systematic review and meta-analysis describing the prevalence of IRIS in patients with different opportunistic infections. The overall prevalence of IRIS was 16.1% (11.1-22.9) in unselected patients starting ART, and 4.5% (2.1-8.6) of patients with any type of IRIS died. Meta-regression analyses showed that the risk of IRIS is associated with CD4 cell count at the start of ART, with a high risk in patients with fewer than 50 cells per μL . Occurrence of IRIS might therefore be reduced by initiation of ART before immunodeficiency becomes advanced.
- Powell K, Davis JL, Morris AM, Chi A, Bensley MR, Huang L. Survival for patients with HIV admitted to the ICU continues to improve in the current era of combination antiretroviral therapy. *Chest.* 2009;135:11-17.
- Sixth in a series of articles from San Francisco General Hospital documenting ICU epidemiology and mortality of HIV-infected patients throughout the course of the AIDS epidemic. In the most recent era of combination ART, respiratory failure remained the most common indication for ICU admission (42% overall). The proportion of patients with respiratory failure decreased each year from 52% to 34% ($P = 0.02$), and hospital survival ratios significantly increased during the 5-year period ($P = 0.001$). ART use at ICU admission was not associated with survival, but it was associated with higher CD4 cell counts, lower plasma HIV RNA levels, higher serum albumin levels, and lower proportions of patients with AIDS-associated ICU admission diagnoses and with *Pneumocystis pneumonia*.
- Walzer PD, Evans HE, Copas AJ, Edwards SG, Grant AD, Miller RF. Early predictors of mortality from *Pneumocystis jirovecii* pneumonia in HIV-infected patients: 1985-2006. *Clin Infect Dis.* 2008;46:625-633.
- This study is the largest retrospective study to date of 494 consecutive patients with 547 episodes of laboratory-confirmed PCP and identified risk factors for mortality on or soon after admission. Overall mortality was 13.5%. Multivariate analysis identified factors associated with risk of death, including increasing patient age (adjusted odds ratio [AOR], 1.54; 95% CI, 1.11-2.23; $P = 0.011$), subsequent episode of PCP (AOR, 2.27; 95% CI, 1.14-4.52; $P = 0.019$), low hemoglobin level at hospital admission (AOR, 0.70; 95% CI, 0.60-0.83; $P < 0.001$), low partial pressure of oxygen breathing room air at hospital admission (AOR, 0.70; 95% CI, 0.60-0.81; $P < 0.001$), presence of medical comorbidity (AOR, 3.93; 95% CI, 1.77-8.72; $P = 0.001$), and pulmonary Kaposi sarcoma (AOR, 6.95; 95% CI, 2.26-21.37; $P = 0.001$). Patients with a first episode of PCP were sicker (mean partial pressure of oxygen at admission \pm standard deviation, 9.3 ± 2.0 kPa) than those with a second or third episode of PCP (mean partial pressure of oxygen at admission \pm standard deviation, 9.9 ± 1.9 kPa; $P = 0.008$), but mortality among patients with a first episode of PCP (12.5%) was lower than mortality among patients with subsequent episodes of PCP (22.5%) ($P = 0.019$). While mortality decreased in the ART era, no patient was receiving highly active antiretroviral therapy before presentation with PCP, and none began highly active antiretroviral therapy during treatment of PCP; thus the trend toward improved outcome after June 1996 occurred in the absence of highly active antiretroviral therapy.
- Zalopa A, Andersen J, Powderly W, et al. Early antiretroviral therapy reduces AIDS progression/death in individuals with acute opportunistic infections: a multicenter randomized strategy trial. *PLoS One.* 2009;4:e5575.
- Randomized strategy trial of "early ART" given within 14 days of starting treatment for an acute opportunistic infection (OI) versus "deferred ART" given after OI treatment was completed. There was no statistically significant difference in primary outcomes at 48 weeks (death/AIDS progression or HIV progression with complete or incomplete viral suppression), but the early ART arm did have fewer AIDS progression/deaths (hazard ratio [HR] 0.51; 95% CI, 0.27-0.94) and a longer time to AIDS progression/death (stratified HR 0.53; 95% CI, 0.30-0.92). The early ART arm also had a shorter time to achieving a CD4 count over 50 cells/mL ($P < 0.001$) and no increase in adverse events.

■ EPIDEMIOLOGY

The World Health Organization (WHO) estimates that one-third of the world's population is latently infected with *Mycobacterium tuberculosis*.¹ From this pool, approximately 9 million active tuberculosis (TB) cases emerge annually, resulting in 1.5 million deaths and making TB the second leading cause of death by an infectious agent worldwide.^{2,3} The majority of TB cases (95%) occurs in the developing world. Incidence rates exceed 300 cases per 100,000 persons in most countries in sub-Saharan Africa as well as in Burma and Cambodia; rates are 100-300 cases per 100,000 persons in South Asia, rest of Southeast Asia, Russia and neighboring countries, several countries in South America, and many parts of Africa.^{1,4} Areas with the most cases per year include India (2.0 million cases per year) and China (1.3 million cases per year).

In the United States, the TB rate continues to decline, with 3 new cases per 100,000 reported in 2013, the lowest rate recorded since national reporting began in 1953.⁵ Foreign-born persons and racial/ethnic minorities bear a disproportionate burden of TB in the United States; for example, in 2013, the TB rate within foreign-born individuals—notably Hispanics and Asians—in the United States was 13 times higher than within U.S.-born persons.^{5,6} Among U.S.-born racial and ethnic groups, the greatest racial disparity in TB rates is seen in African-Americans, who have a TB incidence rate that is 6 times higher than U.S.-born whites.⁵ Other groups at increased risk of active TB include prisoners, homeless persons, and human immunodeficiency virus (HIV)-positive individuals.⁵

The acquired immunodeficiency virus (AIDS) epidemic has contributed significantly to the rise in TB cases worldwide, with approximately 1.5 million individuals with active TB per year co-infected with HIV.² HIV increases the risk of developing TB by 21-fold in countries where the prevalence of HIV is more than 1% in the general population.⁷

■ DRUG-RESISTANT TUBERCULOSIS IS A FORBIDDING PROBLEM

Drug-susceptible TB is readily curable provided adherence to medications is followed. However, TB due to *M. tuberculosis* strains with resistance to one or more first-line agents often requires a significantly longer course of antibiotics; second-line agents have more difficult-to-tolerate side effects, and the treatment of drug-resistant TB is significantly more challenging. More important, multidrug-resistant TB (MDR-TB)—defined as resistance to at least both isoniazid (INH) and rifampin (RIF), two of the most powerful first-line anti-TB drugs—is associated with significant increase in morbidity and mortality.⁸⁻¹⁰

It is estimated that of the 9 million new cases of TB per year worldwide, 500,000 are due to MDR-TB. While drug-resistant TB is increasing at an alarming rate worldwide, particularly in India and China,¹¹ the percent of MDR-TB cases in the United States decreased between 1991 and 2006 from 3.5% to 1.1%.^{12,13} MDR-TB disproportionately affects foreign-born individuals, accounting for 0.4% of TB cases occurring in U.S.-born persons and 1.3% in foreign-born individuals.⁶

Extensively drug-resistant tuberculosis (XDR-TB) is defined as resistance to INH, RIF, any fluoroquinolone, and to a second-line injectable (amikacin, kanamycin, or capreomycin). XDR-TB has

emerged with a wide geographic distribution including the United States and is associated with poorer treatment outcomes than MDR-TB, especially in those co-infected with HIV.^{11,14-19}

■ TUBERCULOSIS IN THE INTENSIVE CARE UNIT

TB patients requiring ICU care represent 1% to 3% of all patients with active TB. Most studies of TB patients requiring ICU admission are retrospective and frequently include a disproportionate number of HIV-positive individuals. TB should be considered in the differential diagnosis of critically ill patients, particularly in foreign-born individuals who emigrated from countries with a high prevalence of TB. With the increased use of tumor necrosis factor-alpha (TNF- α) antagonists and other immunosuppressive agents, ICU physicians are more likely to encounter patients with nonclassical features of TB. In this chapter, selected critical care issues in TB are discussed. Some disease forms, such as renal and peritoneal TB, are omitted because they are less likely to be seen in the ICU.

■ PULMONARY TUBERCULOSIS

Pulmonary disease is by far the most common manifestation of active TB and of TB requiring ICU admission. Pulmonary disease may be due to the progression of a primary infection or to reactivation disease.

Primary infection occurs following airborne implantation of tubercle bacilli into the lungs. *M. tuberculosis* is transported from the lungs to hilar lymph nodes via infected dendritic cells and then throughout the bloodstream, resulting in secondary occult infections at extrapulmonary sites (Fig. 132-1). While primary infection is usually asymptomatic in adults, it can present with fever, hilar adenopathy, lung infiltrates, pleural effusions, and even severe pulmonary disease that can mimic viral or bacterial pneumonia, potentially delaying the diagnosis of TB. In severely immunocompromised patients, primary TB may be aggressive and become disseminated. Pleural TB, which can present as pleuritis or empyema, is usually a manifestation of primary TB, although it may also occur with reactivation disease. Pleural biopsy specimens are more likely to yield positive cultures than pleural fluid.

In non-TB-endemic countries, most cases of active TB are due to the reactivation of latent TB infection (LTBI). Reactivation tends to occur within the first 2 years of the initial infection and occurs in about 10% of immunocompetent individuals with LTBI. Typically, reactivation TB is a subacute fibrocavitary pneumonia involving the upper lobes and/or superior segments of the lower lobes. However, reactivation TB can involve any organ system and can present in a fulminant fashion with respiratory failure.²⁰

Both primary and reactivation TB can cause bilateral alveolar infiltrates, hypoxic respiratory failure, and acute respiratory distress syndrome (ARDS).^{20,21} Consolidation is the most frequent radiographic pattern of patients with pulmonary TB who are admitted to the ICU.²² Since this radiographic pattern is highly nonspecific, chest x-rays are often not helpful in raising suspicion for TB. Nevertheless, in patients with active TB, consolidation on initial chest radiographs was found to be a stronger, independent predictor for in-hospital mortality than the presence of nodules, interstitial infiltrates, or cavities.²³ One possible reason for this is a delay in diagnosis as clinicians may be more

FIGURE 132-1 ■ Cartoon representation of a primary infection of TB and occult dissemination. Largely asymptomatic, dissemination of *M. tuberculosis* following primary infection occurs when infected mononuclear cells migrate throughout the body, particularly to the lung apices, kidneys, bone growth plates, and vertebrae, resulting in latent infection.

prone to favor nontuberculous bacterial pneumonia in the absence of cavitation or a miliary pattern. Another reason is that consolidation may be an indication of a suboptimal immune response to the infection. Pulmonary gangrene, which carries a mortality of up to 75%, can ensue when rapid progression of infiltrates causes vascular damage and death of lung tissue.²⁴ Other life-threatening complications of pulmonary TB include hemoptysis, spontaneous pneumothorax, broncho-pulmonary fistula, and empyema. Not unexpectedly, delayed recognition and treatment of nosocomial pneumonia complicating TB patients requiring mechanical ventilation have significant adverse effects on survival.^{25,26}

Perhaps the best safeguard to prevent missing a diagnosis of pulmonary or disseminated TB in critically ill patients is to maintain a high index of suspicion of it in at-risk individuals—for example, the foreign-born, immunosuppressed, and/or those known to have a history of untreated LTBI. Studies have shown that the presence of diffuse infiltrates consistent with ARDS and/or acute respiratory failure may cause physicians to inappropriately dismiss the diagnosis of TB.²⁷⁻²⁹ Older individuals (≥ 65 years old) or patients with AIDS may also have a delayed diagnosis of TB due, in part, to atypical presentations.^{30,31}

In-hospital mortality among TB patients who require ICU admission is high, at 26% to 67% and may be higher among those requiring mechanical ventilation, at 48% to 81%.^{23,25,26,32-36} Delayed initiation of anti-TB treatment has been shown to increase mortality.³⁶ Other risk factors for death among TB patients in the ICU are less specific to TB, such as severity of illness, hypoalbuminemia, anemia, lymphopenia, alcoholism, advanced age, and organ failure requiring life support including mechanical ventilation, renal replacement therapy, and use of vasopressors.^{23,25,26,32,33,37,38} Despite being a relatively rare cause of respiratory failure, pulmonary TB requiring ICU care carries a poor prognosis. Early recognition of the infection is essential in reducing mortality and preventing the nosocomial spread of *M. tuberculosis*.²⁹

DISSEMINATED TUBERCULOSIS

Disseminated, or “miliary,” TB is more likely to occur in the very young, the very old, and in patients with underlying diseases such as HIV. It may result from either primary or reactivation TB. Disseminated TB typically presents subacutely with symptoms present for days to months, but can manifest fulminantly with ARDS, septic shock, and multiorgan failure.^{39,40} Typical presenting signs and symptoms include fever, malaise, weight loss, dyspnea, and hypoxia.

The chest radiograph (Fig. 132-2, A) and CT scan (Fig. 132-2, B) show a typical miliary pattern manifested by a profusion of diffuse small (<2 mm) nodules that resemble the size and uniformity of millet seeds (Fig. 132-2, C). In some cases of disseminated disease, the chest x-ray may appear normal. Virtually any organ may be involved, including the adrenals, brain, meninges, liver, gallbladder, pancreas, eyes, urinary tract, and skin. Bone marrow involvement by TB commonly manifests with anemia, leukemoid reaction, and thrombocytosis. The diagnosis of miliary TB can be difficult. If disseminated TB is suspected, sputum smears should be obtained even if lung disease is not apparent. Biopsy and culture of affected tissue(s) such as the bone marrow are often required. Culture of blood, urine, and/or stool may be positive, especially in HIV-positive patients.⁴⁰

NEUROLOGIC TUBERCULOSIS

Tuberculous Meningitis

TB meningitis is rare, accounting for more than 1% of global TB cases, and with only 107 cases reported in the United States in 2013.⁴¹ It occurs via rupture of a subependymal tubercle that seeded and formed during primary infection or disseminated disease. Individuals at high risk of TB meningitis include very young children with primary TB and older patients with immunodeficiency disorders such as HIV. Most will have no known history of TB, but evidence of extrameningeal disease (e.g., pulmonary, urinary, etc.) can be found in about half of the patients.^{42,43}

TB meningitis is typically a subacute disease. Symptoms can be present for 1 day to 9 months with a median of 10 to 14 days prior to diagnosis.^{42,44} A prodromal phase of low-grade fever, malaise, headache, dizziness, vomiting, and/or personality changes may be present for 2 to 3 weeks before patients seek medical care. Typical findings at presentation include worsening headache, altered mental status, stroke, hydrocephalus, and cranial neuropathies. These clinical features are the result of basilar meningeal fibrosis and vascular inflammation.⁴⁵ Classic features of bacterial meningitis, such as stiff neck and fever, may be absent. When allowed to progress, seizures and coma may ensue.

The diagnosis of TB meningitis can be difficult and may be based only on clinical findings without definitive microbiological proof. The tuberculin skin test is positive in only about 50% of patients with TB meningitis. Certain clinical characteristics such as longer duration of symptoms (>6 days), moderate cerebrospinal fluid (CSF) pleocytosis, and the presence of focal deficits increase the probability of TB meningitis.^{46,47} Characteristic CSF findings of TB meningitis include

- Leukocytosis with predominance of lymphocytes. White blood cell counts are usually between 100 and 500 cells/ μ L. Lower white blood cell counts and neutrophil predominance may be seen very early in the course of the disease.
- Elevated protein levels, usually between 100 and 500 mg/dL
- Low glucose levels, typically less than 45 mg/dL

CSF samples should be sent for acid-fast smears, but this has low sensitivity. Because TB meningitis is a paucibacillary disease, centrifuging larger quantities of CSF (10–15 mL) from several lumbar punctures can increase the sensitivity. Culture is also associated with low sensitivity and can take weeks to become positive. A stereotactic biopsy can be performed if tissue samples are needed. Mycobacterial antigens by ELISA or radioimmunoassay have been detected in the

FIGURE 132-2 ■ Miliary TB. **A**, Chest radiograph of a patient with miliary TB. **B**, The chest CT scan of the same patient. Both show the characteristically small, less than 2-mm, nodules that are supposed to resemble **(C)** millet seeds. Note that millet seeds are approximately 2 mm in diameter.

CSF of patients with TB meningitis.⁴⁸ A large study cited sensitivities of 90% for interferon-gamma (IFN- γ) release assay, 82% for automated culture systems, 73% for Lowenstein-Jensen medium, 30% for adenosine deaminase, and 27% for Ehrlich-Ziehl-Neelsen acid-fast staining of the CSF.⁴⁹

In recent years, the use of nucleic acid amplification assays (NAAs) has been shown to aid in the diagnosis of TB meningitis. These tests can detect *M. tuberculosis* in a few hours. Their sensitivity is

FIGURE 132-3 ■ Tuberculous meningitis. T1-weighted **(A)** transverse MRI of the brain and **(B)** sagittal MRI of the base of the brain and the spinal cord in a patient with tuberculous meningitis. Note the enhanced meninges (arrows) in the basilar regions of the brain, brainstem, and spinal cord.

56% to 62%, though it may be as high as 80% among HIV-infected patients, with a specificity of 95% to 98%.⁵⁰⁻⁵² Comparisons of NAAs and microscopy/culture using large volumes of CSF have indicated that the sensitivity of microscopy was similar to that of NAAs for the diagnosis of TB meningitis, and repeated testing gave the highest diagnostic yield.⁵³ The sensitivity of CSF microscopy and culture falls rapidly after the start of treatment, whereas mycobacterial DNA may remain detectable within the CSF up to a month after the start of treatment.⁵⁴ Given the high morbidity and mortality associated with TB meningitis, the most recent WHO recommendations include the use of Xpert MTB/RIF®, a NAA, to be used in preference to conventional microscopy and culture as the initial diagnostic test in patients with suspected TB meningitis.² Regardless of which diagnostic test is used, a negative test neither excludes the diagnosis nor obviates the need for continued empiric treatment if the clinical suspicion is high.⁵⁵

Magnetic resonance imaging (MRI) often reveals a basilar meningeal enhancement (Fig. 132-3) and/or hydrocephalus.⁴³ Hypodensities due to cerebral infarcts and ring- or nodular enhancing lesions can also be seen. MRI is superior to computed tomography for evaluating the brainstem and the extent of lesions.

The outcome of TB meningitis is improved by timely treatment. Thus, empiric treatment is warranted when risk factors and clinical features are suggestive of TB meningitis, even before microbiological confirmation. Chemotherapy for TB meningitis follows the model of short-course chemotherapy for pulmonary TB—an induction phase, followed by a continuation phase. However, unlike pulmonary TB, the optimal drug regimen and duration of each phase of treatment are not clearly established. INH and RIF remain the most essential drugs. INH penetrates the CSF freely and has potent early bactericidal activity.⁵⁶⁻⁵⁸ RIF penetrates the CSF less well (maximum concentrations around 30% of plasma), but the high mortality from RIF-resistant TB meningitis has confirmed its central role in the treatment of central nervous system (CNS) disease.⁵⁹ One study compared standard oral doses of RIF (450 mg) to higher doses of RIF (600 mg) administered intravenously. The higher dose RIF group had three times higher CSF concentrations than the standard oral dose group as well as improved mortality (35% vs. 65%).⁶⁰ INH, RIF, and pyrazinamide are considered mandatory at the beginning of TB meningitis treatment, and some centers use all three drugs for the duration of therapy.⁶¹ There are no data from controlled trials to guide the choice of the fourth drug. Most

authorities recommend either streptomycin or ethambutol, although neither penetrates the CSF well in the absence of inflammation, and both can produce significant adverse reactions. Therapy should be continued for 9 to 12 months.

Adjunctive corticosteroid treatment of TB meningitis has been recommended for more than 50 years, but there has been long-standing concern that corticosteroids may reduce the penetration of anti-TB drugs into the CNS.⁴⁵ A Cochrane systematic review and meta-analysis of seven randomized controlled trials involving 1140 participants (with 411 deaths) concluded that corticosteroids improved outcome in HIV-negative children and adults with TB meningitis but that the benefit in HIV-infected individuals remains uncertain.⁶² The results were heavily influenced by a study performed in 545 Vietnamese adults with TB meningitis, which observed that treatment with dexamethasone was associated with a significantly reduced risk of death.⁶³ However, there was no demonstrable improvement in the combined end point of death or severe disability at the 9-month follow-up. The survival benefit associated with corticosteroid therapy may have been due, in part, to a reduction in severe adverse events (9.5% vs. 16%), particularly hepatitis, that necessitated changes in anti-TB drug regimens. No mortality benefit from dexamethasone was evident in 98 HIV-infected patients included in the study.⁶³

Since there are no controlled trials comparing different corticosteroid regimens, the choice of regimen should be based on those found to be effective in published trials. One recommended regimen for adults is dexamethasone 12 mg a day for 3 weeks, followed by a gradual taper over the next 3 weeks.⁶⁴ In a large study from Vietnam, patients with mild disease received intravenous dexamethasone 0.3 mg/kg/day \times 1 week, 0.2 mg/kg/day \times 1 week, and then 4 weeks of tapering oral therapy.⁶³ For patients with severer TB meningitis, intravenous dexamethasone was given for 4 weeks (1 week each of 0.4 mg/kg/day, 0.3 mg/kg/day, 0.2 mg/kg/day, and 0.1 mg/kg/day), followed by 4 weeks of tapering oral dexamethasone therapy.⁶³

The prognosis of TB meningitis largely depends on the neurologic status at the time of presentation and time to treatment initiation. Most patients will die in 5 to 8 weeks if not treated. Various case series indicate a mortality rate between 7% and 65% in developed countries and up to 69% in underdeveloped areas.^{42,43,65} Neurologic sequelae occur in up to 50% of survivors.⁶⁵ Mortality risk is the highest in those who are elderly and with comorbidities, severe neurologic involvement on admission, and rapid progression of disease.

Other Central Nervous System Manifestations of Tuberculosis

Other CNS manifestations of TB include brain abscesses, intracranial tuberculomas, vasculitis, radiculomyelitis, and spinal arachnoiditis. These can occur in conjunction with TB meningitis but are less likely to be seen in the ICU when isolated. Intracranial tuberculomas are more common among pediatric patients, especially infants, and can occur in any region of the brain. They result from hematogenous spread of TB. Tuberculous radiculomyelitis is a paradoxical reaction to the treatment of TB meningitis and may respond to corticosteroids. Signs and symptoms include subacute paraparesis, radicular pain, bladder disturbance, and paralysis.⁶⁶

CARDIOVASCULAR TUBERCULOSIS

Tuberculous Pericarditis

Pericarditis is an uncommon, but important, manifestation of TB. In countries with a low incidence of TB, it is primarily a disease among the elderly and those with HIV, but it should be considered as a differential diagnosis of any patient with pericarditis and/or pericardial effusion. Tuberculous pericarditis can result from local spread from the lungs, tracheobronchial tree, lymph nodes, or adjacent bones or by disseminated infection. The onset is usually insidious. Presenting signs and symptoms can be nonspecific (fever, dyspnea, and weight loss)

and/or more specific to the pericardium, such as characteristic pericardial chest pain. Large hemorrhagic effusions may develop, resulting in cardiac tamponade. Pericardial inflammation and thickening may eventually cause constrictive pericarditis. The presence of both pericardial effusion and constrictive pericarditis is physiologically characterized by the continued elevation of diastolic pressure after pericardiocentesis. Such a finding should raise suspicion for tuberculous pericarditis.

The diagnosis of tuberculous pericarditis can be difficult to prove. Culture of pericardial fluid is positive in only 30% of cases, and pericardial biopsy has a yield of approximately 60%. Biopsy of the pericardium may reveal granulomatous changes consistent with TB or stain positive for acid-fast bacteria. The presence of elevated adenosine deaminase levels in the pericardial fluid has been shown to indicate tuberculous pericarditis, but confirmation is needed.⁶⁷ PCR holds promise as a more sensitive test in the diagnosis of tuberculous pericarditis.^{68,69} Many individuals are treated empirically for tuberculous pericarditis based on clinical suspicion, positive tuberculin skin test results, imaging studies, and exudative pericardial fluid with high protein and mononuclear white count. Treatment involves standard four-drug regimens as for other manifestations of TB. Prednisone 60 mg a day, tapered off over 11 weeks, is sometimes used in addition to anti-TB treatment and has been shown to reduce the need for operative intervention.⁷⁰ Further study of corticosteroid use in tuberculous pericarditis is ongoing.⁷¹ Pericardiectomy is sometimes necessary in the treatment of refractory or recurrent disease.

Other Cardiovascular Manifestations of Tuberculosis

In addition to the pericardium, TB may also affect the myocardium, endocardium, and epicardium (coronary arteries). These disorders are very rare. Tuberculous myocarditis occurs via direct spread from pericardial or mediastinal lymph nodes or from disseminated disease.⁷² Endocardial involvement may manifest as endocarditis or as mural thrombi with entrapped *M. tuberculosis*. TB may also affect the coronary arteries, resulting in coronary arteritis with granulomatous inflammation of the arterial wall and obliterative intimal fibrosis.⁷³

The aorta can be affected by TB, causing aortitis, aortointestinal fistula formation, or rupture.^{74,75} The pathogenesis of aortitis includes septic embolization from endocarditis, seeding of a preexisting aneurysm from bacteremia, or extension from a contiguous site of infection. Signs and symptoms include fever, abdominal or back pain, and a palpable abdominal mass. Blood cultures are positive for *M. tuberculosis* in approximately 15% of cases. CT findings include air in the aortic wall, a periaortic nodularity, a saccular aneurysm in a non-calcified aorta, and a rapidly increasing aortic diameter. A primary mycotic aneurysm of the aorta may be a sequela of chronic tuberculous aortitis.^{76,77}

TUBERCULOSIS IN HUMAN IMMUNODEFICIENCY VIRUS-POSITIVE PATIENTS

HIV is the most important host risk factor for active TB.⁷⁸ In many developing countries, TB is the most common opportunistic infection associated with HIV. The estimated annual risk of active TB among persons with LTBI in the general population is 12.9 per 1000 person-years. In contrast, rates of progression to active TB among HIV-infected persons with LTBI range from 35 to 162 per 1000 person-years. More recent estimates for reactivation TB in HIV-positive individuals shows a rate ratio of 57 (95% CI, 27-120) compared to HIV-negative individuals with LTBI.⁷⁹ Since TB may be an initial manifestation of HIV infection, all patients with TB should be tested for HIV. The WHO estimates that globally, 13% of TB patients in 2013 were co-infected with HIV and that HIV co-infected patients accounted for over 25% of deaths from TB.²

The mechanism of increased TB susceptibility in HIV-positive persons is incompletely understood. Unlike other AIDS-related opportunistic infections, the CD4⁺ count is not always a reliable predictor of increased risk of TB disease, albeit CD4⁺ lymphopenia would reduce IFN γ production, impairing macrophage and dendritic cell activation. Alveolar macrophages (AMs) are important components of an effective immune response to TB,⁸⁰ and AM apoptosis represents a critical host defense mechanism that promotes *M. tuberculosis* elimination. In this context, another possible mechanism by which HIV increases susceptibility to TB is that HIV-infected AMs have a reduced apoptotic response to *M. tuberculosis* compared to AMs from healthy individuals.^{81,82}

When the CD4⁺ count is above 350 cells/ μ L, pulmonary TB in AIDS patients is more likely to present with typical chest radiograph findings of upper lobe fibrocavitary disease.⁸³ However, as the CD4⁺ count decreases, pulmonary TB tends to manifest with more atypical radiographic manifestations, such as mediastinal adenopathy, diffuse miliary or nodular infiltrates, focal lower zone infiltrates, and lack of cavitation.⁸³ Among HIV-positive persons, death from TB was significantly associated with low CD4⁺ counts.²⁵ While co-infection with HIV is considered to contribute significantly to TB-related mortality, a study showed no difference in mortality in TB patients requiring ICU care between those who were HIV negative and those with advanced AIDS in a low-burden, resource-rich country where state-of-the-art intensive care is available, suggesting that the severity of illness has a greater influence on mortality than the HIV status per se.²⁵ Extrapulmonary TB is more common among HIV-positive patients, occurring in up to 70% of patients. Disease involving the lymph nodes is especially common. Other extrapulmonary manifestations include miliary disease, sepsis, and CNS disease.^{30,84} Empiric treatment may be necessary before the diagnosis is confirmed. If rapid diagnosis is needed, NAAs can be used, although they are more accurate in smear-positive cases.

After initiating highly active antiretroviral therapy (HAART) in severely immunosuppressed patients, those with subclinical or recently diagnosed TB may display a paradoxical reaction, where there is an apparent clinical worsening of TB while on appropriate anti-TB treatment.⁸⁵⁻⁸⁷ This phenomenon, also known by the more descriptive name of *immune reconstitution inflammatory syndrome* (IRIS), can manifest as early as 7 days after starting HAART. Signs and symptoms include fever, weight loss, and evidence of local inflammatory reactions such as lymphadenitis and worsening pulmonary disease such as increased pulmonary consolidation, nodules, and effusions. Histologically, a vigorous suppurative and necrotizing granulomatous reaction occurs, with or without caseation; cultures of infected material are almost invariably positive.

Treatment of TB in patients with HIV is similar to that in HIV-negative patients but is often complicated by drug interactions between TB medications and antiretrovirals.⁸⁸ Protease inhibitors and nonnucleoside reverse transcriptase inhibitors can either induce or inhibit activity of the P450-3A (CYP3A) system. RIF can increase the activity of CYP3A, leading to decreased levels of several antiretrovirals. Rifabutin is a less potent inducer of the CYP3A system and is associated with fewer drug-drug interactions, but dose adjustments may be needed. Despite these potential drug interactions, an RIF-based regimen should be used whenever possible. Patients with liver disease such as hepatitis C may be at increased risk of drug-induced hepatotoxicity. Another treatment issue in HIV-TB co-infection is that patients may fail to properly absorb the anti-TB drugs, which may increase the risk of treatment failure, relapses, and acquired drug resistance.⁸⁹

Because of the increased risk of RIF resistance, patients with HIV should *not* receive once weekly INH-rifapentine in the continuation phase of treatment. Twice weekly INH-RIF or INH-rifabutin should be avoided when the CD4⁺ cell count is less than 100 cells/ μ L. Treating drug-susceptible pulmonary TB in HIV-positive individuals for 9 months rather than the standard 6 months is associated with lower relapse rates.^{90,91} Recommendations regarding the treatment of TB in HIV patients are frequently revised as new drugs and information

become available. The following websites can assist with treatment decisions and information on drug-drug interactions:

- http://www.cdc.gov/tb/publications/guidelines/TB_HIV_Drugs/default.htm
- <http://www.medscape.com/updates/quickguide>
- <http://www.nationaltbcenter.edu/>

If a patient develops IRIS while on HAART, it is generally recommended that HIV therapy be continued during TB treatment whenever possible because IRIS is usually self-limited. However, more severe IRIS may require the addition of corticosteroids and/or temporary discontinuation of HAART. Patients with the lowest CD4⁺ counts, less than 50 cells/ μ L, are at highest risk of severe IRIS with the initiation of HAART, though they also have the greatest mortality benefit with early HAART initiation.^{92,93} There is ongoing debate as to the safest time for the initiation of HAART following the start of TB treatment.^{92,94,95} The WHO currently recommends the initiation of HAART, for those not already on it, within 8 weeks of TB treatment initiation.

TUBERCULOSIS AND IMMUNOMODULATORY THERAPIES

TNF- α plays a central role in the pathogenesis of various inflammatory disorders and in the pathophysiologic response to many infections. TNF- α is produced predominantly by macrophages and lymphocytes and is active both as a membrane-bound and soluble protein.^{96,97} In several animal models, TNF- α plays an essential part in the host response to TB.⁹⁸ One mechanism by which TNF- α potentiates the host defense is by its ability to induce apoptosis of infected cells. Macrophage apoptosis helps contain *M. tuberculosis* by maintaining granuloma integrity, increasing the efficiency of antigen presentation, and promoting the killing of intracellular *M. tuberculosis*.⁹⁹ Administration of antibodies neutralizing TNF- α resulted in the reactivation of TB in a mouse model.¹⁰⁰ Interruption of the normal TNF- α -controlled response to TB reduces apoptosis, disrupts granuloma integrity, and predisposes to disseminated infection.

TNF- α antagonists are increasingly used for the treatment of various chronic inflammatory disorders. Currently licensed TNF- α antagonists fall into two main types: monoclonal neutralizing anti-TNF- α antibodies and soluble p75 subunits of the TNF- α receptor (TNF- α -R). The soluble TNF- α -Rs antagonize TNF- α function by acting as decoys to bind TNF- α . Four monoclonal anti-TNF- α antibodies (infliximab, adalimumab, certolizumab pegol, and golimumab) and two TNF- α -Rs (etanercept and abatacept) are in clinical use. Patients treated with TNF- α -blockers have a TB incidence rate of 1.17 per 1000 patient-years—12.2 times that of the general population¹⁰¹; almost all these cases are due to the reactivation of LTBI. A consensus statement reported that the relative risk for reactivation TB is increased 25-fold in individuals who use TNF- α antagonists compared to that in nonusers.¹⁰²

Important differences have emerged among the TNF- α antagonists in regard to the risks of reactivation TB. Consistently, the excess risk is associated with infliximab and adalimumab rather than etanercept. For example, compared with etanercept, infliximab is associated with a two- to seven-fold greater risk of TB, shorter time to TB onset (17 vs. 48 weeks), and a higher proportion of TB cases with disseminated or extrapulmonary disease (25% vs. 10%).^{103,104} It is not entirely clear why the neutralizing antibodies to TNF- α put people at greater risk of reactivation TB than soluble TNF- α receptors. Possible reasons include a longer duration of action of infliximab and adalimumab and their ability to bind to membrane-bound TNF- α with greater affinity than etanercept.⁹⁶ As a result, infliximab can induce death in T cells that express the membrane-bound TNF- α , whereas etanercept cannot. In addition, anti-TNF- α antibodies can inhibit T-cell activation and IFN- γ production, whereas etanercept cannot. Thus, the pharmacokinetic and biological differences between the two main types of TNF- α antagonists may account for the greater susceptibility to intracellular pathogens with the use of the anti-TNF- α antibodies.^{96,105} As might be anticipated, when anti-TNF- α antibodies are used in combination

with other immunosuppressive medications such as methotrexate or azathioprine, the risk of TB reactivation is higher than that with the use of anti-TNF- α antibodies alone.¹⁰⁶

Antagonists to other inflammatory cytokines are also being used in the management of patients with rheumatologic and inflammatory disorders. Interleukin-1 (IL-1) receptor antagonist (IL-1Ra) is the naturally occurring protein that prevents the action of IL-1 α and IL-1 β by competitively binding to IL-1R. Anakinra is a recombinant human form of IL-1Ra. In a case report, anakinra was associated with reactivation TB.¹⁰⁷

■ DIAGNOSIS OF TUBERCULOSIS

When TB is suspected, the first diagnostic test should be a microscopic examination and culture for mycobacteria of relevant body fluids or tissues. Several specimens are often required, especially for CNS disease.

Patients with suspected pulmonary TB should be placed in respiratory isolation until three sputa, collected by at least 8 hours between samples, are negative for acid-fast bacteria. Since patients with extrapulmonary disease may also have occult pulmonary disease, it is generally recommended that sputum smears be sent for these patients regardless of chest radiographic findings.

Since acid-fast smear does not differentiate between *M. tuberculosis* and nontuberculous mycobacteria, culture is used to confirm species and determine drug susceptibility. Simultaneous culture on both liquid and solid media is recommended. Liquid medium such as newer BACTEC systems allow growth of the organism in about 14 days, whereas growth takes 3 to 6 weeks on solid media (Lowenstein-Jensen or Middlebrook 7H11). Once sufficient growth is obtained, species identification can be obtained via conventional biochemical tests or more rapid tests such as nucleic acid probes, high-performance liquid chromatography, the NAP test (p-nitro- α -acetylamino- β -hydroxypropionophenone), or molecular tests. Only experienced laboratories should complete susceptibility testing on culture-positive specimens. Molecular fingerprinting by restriction fragment length polymorphism can be used to distinguish strain types when laboratory contamination is suspected.

Although rapid and inexpensive, acid-fast smear microscopy is limited by its poor sensitivity (approximately 50% sensitivity in culture-confirmed pulmonary TB cases) and suboptimal specificity (50%-80%) in settings where nontuberculous mycobacteria are commonly isolated.¹⁰⁸⁻¹¹⁰ NAAs have become a routine procedure in many settings because they can reliably detect *M. tuberculosis* in specimens

1 or more weeks earlier than culture.¹⁰⁹ Because of the increasing use of NAAs and the potential impact on patient care and public health, the Centers for Disease Control (CDC) and the Association of Public Health Laboratories made recommendations for using NAAs for laboratory confirmation of TB. The CDC recommends that NAAs be performed on at least one respiratory specimen from each patient in whom a diagnosis of TB is being considered but has not yet been established and for whom the test result would alter case management or TB control activities.^{111,112}

■ TREATMENT OF TUBERCULOSIS

Standard treatment of adults with drug-susceptible TB is a three- or four-drug regimen for at least 6 months.^{113,114} The typical course of therapy for drug-susceptible disease is 2 months of INH, RIF, pyrazinamide (PZA), and ethambutol (EMB) (initial phase), followed by 4 months of INH and RIF (continuation phase) (Tables 132-1 and 132-2). A 9- to 12-month regimen is suggested for TB meningitis, for pulmonary TB that is slow to respond to therapy such as those with

TABLE 132-1

Current Regimens for Treatment of Drug-Susceptible TB

| REGIMEN | INITIAL PHASE | CONTINUATION PHASE |
|--------------------------------|---|--|
| DAILY or 5 days per week | 8 weeks of INH, RIF, PZA, \pm EMB | 18 weeks of INH and RIF |
| INTERMITTENT | a) 2 weeks of daily INH, RIF, PZA, and EMB (or SM), then 6 weeks of INH, RIF, PZA, EMB BIW or TIW b) 8 weeks of thrice-weekly INH, RIF, PZA, and EMB (or SM) | 18 weeks of INH and RIF BIW 18 weeks of INH and RIF TIW |

The daily regimen is employed when patients self-administer their drugs. There is enough redundancy that, if patients miss some of their doses, the outcome will remain acceptable. The intermittent regimens are intended for DOT. Regimen (a) entails a total of 62 doses and has yielded over 95% success rates.¹²⁸ Regimen (b) involves 78 doses and has also resulted in success rates of approximately 95% in Hong Kong where it is the standard regimen.¹²⁹ BIW, twice weekly; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; SM, streptomycin; TIW, thrice weekly.

TABLE 132-2 Dosages of First-line Antituberculosis Drugs (in Adults) and Major Adverse Effects

| DRUG | DAILY DOSAGE | TWICE OR THRICE WEEKLY DOSAGE | ADVERSE EFFECTS |
|---------------|---|--------------------------------------|--|
| Isoniazid | 5 mg/kg oral (max: 300 mg) | 900 mg BIW 600 mg TIW | Hepatitis, peripheral neuritis, drug-induced lupus, seizures, and hypersensitivity with rash and fever. Drug interactions with dilantin and disulfiram. Pyridoxine can decrease neurotoxicity. |
| Rifampin | 10 mg/kg oral (max: 600 mg) | 10 mg/kg 600 mg BIW 600 mg TIW | Orange body secretions, flu-like syndrome, hepatitis, pruritus, thrombocytopenia, nausea, anorexia, diarrhea, renal failure, and multiple drug interactions |
| Rifabutin* | 10 mg/kg oral (max: 300 mg) | 5 mg/kg | Neutropenia, uveitis, hepatotoxicity, orange discoloration of body fluids |
| Rifapentine** | 10 mg/kg once WEEKLY (max: 600 mg) | | Similar to rifampin |
| Pyrazinamide | 15-30 mg/kg oral (max: 2.0 gm) | 30-35 mg/kg | Hyperuricemia, hepatitis, rash, nausea, and anorexia |
| Ethambutol | 25 mg/kg initial 2 months, then 15 mg/kg oral | 50 mg/kg BIW 30 mg/kg TIW | Optic neuritis and gastrointestinal discomfort |

*Rifabutin and rifapentine are considered first-line agents when intolerance to rifampin precludes its use or concerning drug interactions exist.

**Rifapentine is only used in a once-weekly dose in HIV-negative patients with noncavitary and uncomplicated disease. It is not approved for use in children.

BIW, twice weekly; TIW, thrice weekly.

cavitary lesions and persistent sputum culture positivity even after 2 months of an appropriate four-drug regimen, or when PZA is not used in the induction regimen. EMB can be discontinued when drug-susceptibility studies show sensitivity to INH and RIF. Streptomycin can be used instead of EMB if resistance is unlikely or susceptibility is shown. The continuation phase can be daily therapy, twice weekly therapy, or thrice weekly therapy for drug-susceptible TB (see Table 132-1). See the HIV section for details of treating TB in HIV-positive patients. Specific guidelines including information on first- and second-line agents have been published by the CDC.¹¹⁵

When MDR-TB is suspected or confirmed, additional drugs that may be used include amikacin, a fluoroquinolone (levofloxacin, moxifloxacin), capreomycin, ethionamide, cycloserine, para-aminosalicylic acid, and/or linezolid.^{15a} In the absence of prospective, randomized trials, individual patient data meta-analyses have shown that treatment success for MDR-TB is associated with the use of fluoroquinolones, ethionamide, or prothionamide and a greater total number of effective drugs.⁸ Whenever possible, treatment for an MDR-TB strain should be guided by drug-susceptibility testing to EMB, PZA, and the second-line anti-TB drugs.¹¹⁶ While favorable results have been reported with new anti-TB drugs such as bedaquiline and delamanid, it is important to emphasize that efficacy was initially based on the surrogate end point of accelerated culture conversion and not on cure rate or survival¹¹⁷⁻¹²¹; indeed, in a phase 2 trial, there were significantly more deaths when bedaquiline was added to the standard regimen.¹²⁰ Local public health departments should be contacted to meet reporting requirements and will usually be responsible for treatment monitoring. Directly observed therapy should be implemented whenever possible. Patients with MDR-TB require longer therapy (generally 18 months of treatment after the last negative sputum culture). Surgical resection after 2 to 3 months of treatment may improve outcome.¹¹⁵

Parenteral therapy may be required in ICU patients and is recommended for patients with fulminant disease (Table 132-3). When delivered enterally, half of the ICU patients have subtherapeutic levels of RIF.¹²² INH and RIF are available in parenteral forms; EMB and PZA are not. Other active medications available for intravenous use include aminoglycosides, fluoroquinolones, and capreomycin. In patients with renal failure, dose adjustments are required for those taking EMB, PZA, cycloserine, an aminoglycoside, capreomycin, or a fluoroquinolone. INH and PZA should probably be withheld in the setting of severe liver failure. An expert in the treatment of TB should be consulted when treating complicated ICU patients or those with MDR-TB.

Corticosteroids are generally recommended in the treatment of several TB conditions including TB meningitis and pericarditis, as discussed above.¹²³ Their role in patients with respiratory failure due to TB and in patients with severe AIDS-associated TB has not been proven, but many have used corticosteroids for these conditions. Typical therapy includes prednisone at 40 to 80 mg per day, tapered over a few weeks.

RISK TO HEALTHCARE WORKERS

The awareness that caring for TB patients poses a risk to healthcare workers (HCWs) did not emerge until the 1950s and 1960s, when

TABLE 132-3

**Selected Parenteral Medications
Used in Treating Tuberculosis¹¹⁵**

| MEDICATION | PREPARATION | INITIAL DOSAGE IN ADULTS (MAXIMUM DOSAGE) |
|-----------------------|-------------|---|
| Isoniazid | PO, IV, IM | 5 mg/kg/day (300 mg) |
| Rifampin | PO, IV | 10 mg/kg/day (600 mg) |
| Streptomycin | IV, IM | 10-15 mg/kg/day or 750-1000 mg/day |
| Amikacin | IV, IM | Same as above |
| Kanamycin | IV, IM | Same as above |
| Capreomycin | IV, IM | Same as above |
| p-aminosalicylic acid | PO, IV | 8-12 g/day in 2 or 3 doses |
| Levofloxacin | PO, IV | 500-1000 mg/day |
| Moxifloxacin | PO, IV | 400 mg/day |

Notes: Table shows routine daily dosing. Dosages may differ in children and in patients in intermittent therapy. Persons over age 59 should receive the lower dose for aminoglycosides (750 mg).

IM, intramuscular; IV, intravenous; PO, oral.

studies established that *M. tuberculosis* infection was transmitted by the airborne route.¹²⁴ However, occupational transmission received little attention until numerous outbreaks of TB and MDR-TB occurred in U.S. and European hospitals in the late 1980s and early 1990s.¹²⁵ At that time, more than 20 HCWs became ill with MDR-TB, and at least 10 died.¹²⁶ Hundreds of HCWs may be latently infected with MDR-TB and thus represent a relatively large reservoir of individuals at risk of future reactivation MDR-TB.

Pulmonologists are at higher risk of occupational exposure to TB than other medical specialists. Atypical presentations of TB can put providers at increased risk when TB is not suspected and proper precautions are not taken.¹²⁷ Bronchoscopy requires close contact with patients and provokes coughing, which likely contributes to the tuberculin skin test conversion rate of 11% among pulmonary fellows.¹²⁷ DMF-HEPA respirators should be used when performing bronchoscopy on patients with known or suspected TB.¹²⁷

In HCWs with negative tuberculin skin test reactions who undergo repeat testing, an increase in reaction size of more than 10 mm within a period of 2 years should be considered a skin-test conversion indicative of recent infection with *M. tuberculosis*. Since tuberculin skin test conversion typically occurs 3 to 8 weeks after primary infection, skin testing should be performed at 3 weeks following exposure.

HCWs with potential exposure should be monitored for symptoms, and unless they are known to have a positive tuberculin skin test at baseline, skin testing or an IFN- γ release assay should be performed as soon as possible after the exposure to establish a baseline. If initial screening is negative, testing should be repeated 8 to 10 weeks following exposure, and if found to be positive, treatment for LTBI is recommended.

KEY POINTS

- Whereas pulmonary TB classically develops cavitary lung disease, it can present in many ways, including ARDS and respiratory failure.
- Tuberculous meningitis typically has a subacute presentation and has a high mortality rate, which is improved with prompt treatment.
- Tuberculous pericarditis is rare but can result in constrictive pericarditis or cardiac tamponade from a hemorrhagic effusion.
- Disseminated TB can affect nearly any organ and is most common in very young or old patients and those who are immunocompromised.

KEY POINTS—cont'd

5. Patients with HIV and those on anti-TNF therapies are at increased risk of developing active TB.
6. Culture remains the cornerstone of diagnosis of TB and is important for drug resistance testing. However, nucleic acid amplification assays can provide a much more rapid diagnosis and are especially recommended for use with CSF and other fluids where culture positivity is classically low, such as pericardial and pleural fluid.
7. Treatment of TB requires several drugs given over many months, though the exact regimen will vary depending on the site of disease and the susceptibility of the cultured organism.
8. Treating with a course of steroids is recommended to reduce morbidity and mortality from TB meningitis and TB pericarditis.

ANNOTATED REFERENCES

- Chan ED, Strand MJ, Iseman MD. Treatment outcomes in extensively resistant tuberculosis. *N Engl J Med* 2008;359:657-9.
This study compared the outcomes of MDR-TB vs. XDR-TB patients at a referral hospital in the United States. Odds ratios for long-term treatment success was 21.1 (MDR-TB vs. XDR-TB). The hazard ratio of death from TB was 7.9 (XDR-TB vs. MDR-TB). Despite aggressive treatment, XDR-TB was associated with significantly poorer long-term outcome and survival than MDR-TB.

Dexamethasone for the treatment of tuberculous meningitis in adolescents and adults. *N Engl J Med* 2004;351:1741-51.
This is a prospective, randomized, placebo-controlled trial of adjunctive dexamethasone in 545 patients over 14 years of age with tuberculous meningitis in two hospitals in Vietnam. The results showed that adjunctive treatment with dexamethasone reduced mortality, but there was no demonstrable improvement in the combined end point of death or severe disability after 9 months.
- Erbes R, Oettel K, Raffenberg M, Mauch H, Schmidt-Ioanas M, Lode H. Characteristics and outcome of patients with active pulmonary tuberculosis requiring intensive care. *Eur Respir J* 2006;27:1223-8.
Retrospective study from Germany looking at 58 TB patients admitted to ICU. The in-hospital mortality was 15 of 58 (25.9%); 13 (22.4%) patients died in the ICU. The factors independently associated with mortality were acute renal failure, need for mechanical ventilation, chronic pancreatitis, sepsis, acute respiratory distress syndrome, and nosocomial pneumonia.
- Tubach F, Salmon D, Ravaud P, Allanore Y, Goupille P, Bréban M, Pallot-Prades B, Pouplin S, Sacchi A, Chichemanian RM, Bretagne S, Emilie D, Lemann M, Lortholary O, Mariette X. Risk of tuberculosis is higher with anti-tumor necrosis factor monoclonal antibody therapy than with soluble tumor necrosis factor receptor therapy: the three-year prospective French Research Axed on Tolerance of Biotherapies registry. *Arthritis Rheum* 2009;60:1884-94.
This is a case-control study investigating the risk of newly diagnosed TB associated with the use of anti-TNF agents. Authors identified 69 cases of TB in patients treated for various inflammatory diseases with infliximab (n = 36), adalimumab (n = 28), and etanercept (n = 5). In the case-control analysis, exposure to infliximab or adalimumab versus etanercept was an independent risk factor for TB (odds ratio [OR] 13.3 [95% CI, 2.6-69.0] and OR 17.1 [95% CI, 3.6-80.6], respectively).
- Nahid P, Gonzalez LC, Rudoy I, de Jong BC, Unger A, Kawamura LM, Osmond DH, Hopewell PC, Daley CL. Treatment outcomes of patients with HIV and tuberculosis. *Am J Respir Crit Care Med* 2007;175:1199-1206.
The optimal length of tuberculosis treatment in patients coinfectd with HIV is unknown. HIV-infected patients who received a 6-month rifamycin-based course of tuberculosis treatment or who received intermittent therapy had a higher relapse rate than HIV-infected subjects who received longer therapy or daily therapy, respectively. Standard 6-month therapy may be insufficient to prevent relapse in patients with HIV.

Although the spectrum of possible “tropical” infections in a patient with exposures overseas may initially seem daunting, a detailed history of the patient’s travel itinerary, activities, and exposures can often significantly narrow the differential diagnosis (Table 133-1). This must include more than simply recording the countries to which the patient traveled. Exposures of a business traveler staying at hotels and dining in fine restaurants in a major city may differ dramatically from those of a student backpacking through rural areas of the same country. Knowledge of the diseases endemic in a given area and their incubation periods and drug resistance patterns is vital (Fig. 133-1 and Table 133-2). In addition, most nontropical infections are common in developing countries. Thus, although the differential diagnosis must be expanded to include tropical diseases, common illnesses seen in developing and industrialized countries must also be considered.

People prone to malaria can be divided into three groups: (1) nonimmune persons having no history of exposure to malaria—primarily tourists and young children, regardless of geographic origin—after the waning of maternal antibodies (around age 6 months); (2) immune or semi-immune persons residing in tropical countries who are repeatedly exposed; and (3) those originally from tropical countries but now residing elsewhere who, in the absence of continued exposure, have waning immunity. The degree of immunity may exert profound effects on the presentation and severity of illness. For example, a returning traveler may develop severe malaria at a relatively low parasitemic load, whereas a resident of sub-Saharan Africa with the same degree of parasitemia may be asymptomatic. Genetic differences in susceptibility may also exist, such as resistance to *Plasmodium vivax* in blacks because of the absence of Duffy antigen, which serves as the receptor, or the relative protection from severe malaria of any species afforded to those carrying the sickle cell trait.¹⁻³

In returning travelers, knowledge of pretravel vaccinations as well as prescribed and taken chemoprophylaxis (which often turn out not to be the same) is imperative. Nevertheless, these preventive measures do not confer 100% protection and should not be used to completely discard a given entity from the differential diagnosis. Both physicians and patients frequently err in the prescribing of and adherence to appropriate prophylactic regimens.^{4,5} Chemotherapy, complete or partial, may prolong the incubation period or alter the presentation of the illness. Those initially from tropical countries are often less likely to seek pretravel medical advice before making a home visit and also often have considerably more exposures to tropical pathogens during their visit than do short-term travelers from industrialized countries.⁶

People living in resource-poor tropical countries are more likely to have complicating health problems but less likely to have been previously diagnosed or controlled. Underlying conditions, such as diabetes, hypertension, malnutrition, chronic anemia, intestinal parasites, tuberculosis, human immunodeficiency virus (HIV), or hepatitis virus infection may be discovered at the time of acute illness.⁷ Infection with multiple tropical pathogens is common in those living in endemic areas. Thus finding a given pathogen cannot automatically be assumed to be the cause of the patient’s current illness.

■ EPIDEMIOLOGY

Malaria parasites are spread to humans by the bite of anopheline mosquitoes. Four species of *Plasmodium* commonly cause malaria in humans: *Plasmodium falciparum*, *P. vivax*, *Plasmodium ovale*, and *Plasmodium malariae* (see Table 133-2). A fifth species, *Plasmodium knowlesi*, is a zoonotic parasite of monkeys found to also cause disease in humans with exposure in the rainforests of Southeast Asia.^{8,9} Furthermore, evidence suggests that there may be distinct species of *P. ovale*.¹⁰ Malaria is the most common serious infection in tropical countries and in returning travelers, and it should therefore be considered in any patient reporting travel to malaria-endemic areas or with exposure to unscreened blood products (“transfusion malaria”) or blood-contaminated needles. Increased travel and immigration have resulted in increases in imported malaria in most industrialized countries.^{11,12}

The most prevalent and dangerous form of malaria is that due to *P. falciparum*. The risk of acquiring *P. falciparum* is highest in sub-Saharan Africa, in particular in West Africa¹³ and New Guinea, moderate in India, and comparatively low in Southeast Asia and Latin America.^{14,15} However, there is increasing recognition that *P. vivax*, the second most common cause of malaria and previously considered to be benign, can also cause severe disease and death.^{16,17} *P. vivax* malaria is especially frequent in travelers returning from Oceania, although the parasite exists in all malaria-endemic regions except Haiti and the Dominican Republic.^{18,19} The dormant liver stage parasites (hypnozoites) that characterize *P. vivax* sometimes result in primary disease or relapse even years after infection. *P. knowlesi*, found in rainforests of Southeast Asia, including parts of Cambodia, China, Indonesia, Laos, Malaysia, Myanmar, the Philippines, Singapore, Thailand, and Vietnam, can also cause severe disease in humans.²⁰⁻²³

Malaria is occasionally reported in individuals without reported travel, usually resulting from the carriage of malaria-infected passengers (who may be asymptomatic) or anopheline mosquitoes on aircraft arriving from endemic areas.²⁴ The parasite may then be secondarily transmitted by anopheline mosquitoes endemic in some industrialized countries, including the United States.

■ PATHOPHYSIOLOGY

P. falciparum accounts for the vast majority of severe malaria because of (1) its ability to infect red blood cells (RBCs) of all ages, resulting in overwhelming parasitemia (up to 70% of RBCs); (2) its induction of adherence of parasitized RBCs to the microvascular wall, with consequent obstruction; (3) its induction of severe metabolic derangements directly through glucose consumption and lactate production and indirectly through the induction of cytokines; and (4) the high prevalence of chloroquine resistance to *P. falciparum* in many parts of the world (see Table 133-2). Nonimmune persons and pregnant women are at greatest risk. Human genetic and parasite strain differences probably play roles in the ultimate course of any given malarial infection.

Unlike the other species of malaria, *P. falciparum* causes decreased RBC deformability and the production of small protrusions or “knobs”

Text continued on p. 937

TABLE 133-1 Some Tropical Diseases That May Merit Management in an Intensive Care Unit*

| DISEASE AND ORGANISM | DISTINGUISHING CLINICAL FEATURES | INCUBATION PERIOD | GEOGRAPHIC DISTRIBUTION | MODE OF TRANSMISSION AND TYPICAL RISK FACTORS |
|--|--|--|---|--|
| NONSPECIFIC FEBRILE SYNDROMES | | | | |
| African trypanosomiasis, hemolympathic stage (<i>Trypanosoma brucei gambiense</i> and <i>brucei rhodesiense</i>) | Lymphadenopathy, HSM, edema, rash; 30% have history of chancre, rarely DIC and thrombocytopenia | 3-21 days | Sub-Saharan Africa | Tsetse fly bite; camping, safari |
| Babesiosis (<i>Babesia</i> spp.) | Hemolytic anemia, HSM | 3-28 days | North America, Europe, sporadic cases worldwide | Tick bite; blood transfusion (rare); especially severe in asplenic persons |
| Brucellosis (<i>Brucella</i> spp.) | Subacute presentation over weeks/months, HSM, weight loss; may involve large bones, joints, and spine | 2-8 weeks | Worldwide, especially Mediterranean, Middle East, and Latin America | Ingestion of contaminated dairy products; respiratory, skin, or conjunctival inoculation from contact with farm animals; abattoir workers, butchers, farmers |
| Candidiasis, disseminated (<i>Candida</i> spp.) | May involve any organ; skin or mucosal lesions not always present | 1-4 weeks | Worldwide | Usually in IH or after administration of long-term antibiotics or maintenance of indwelling catheters |
| Cat scratch disease (<i>Bartonella henselae</i>) | Papule or eschar at the site of inoculation, regional lymphadenopathy, fever may be mild, may progress to CNS involvement or endocarditis | 1-2 weeks | Worldwide | Cat scratch or bite; severe disease most often seen in IH |
| Coccidioidomycosis (<i>Coccidioides immitis</i>) | May see pneumonia with cavities, meningeal, skin, and bone involvement, and eosinophilia | 1-4 weeks, often RD [†] in IH | Desert areas of the Americas | Inhalation of spores from soil; disseminated disease more common in Filipinos, blacks, Hispanics, IH, and in pregnancy |
| Echinococcal cyst, leak, or rupture (<i>Echinococcus</i> spp.) | Allergic symptoms: urticaria, pruritus, and anaphylaxis | Years | Worldwide | Ingestion of eggs in feces of infected carnivores such as dogs and wolves; raising of domestic livestock |
| Ehrlichiosis (<i>Ehrlichia</i> spp.) | Rash (<50%), leukopenia, thrombocytopenia, HSM; may progress to GI, renal, pulmonary, or CNS involvement | 7-21 days | Sporadic foci worldwide | Tick bite; camping, safari |
| Histoplasmosis, disseminated (<i>Histoplasma capsulatum</i>) | Mucocutaneous lesions, lymphadenopathy, HSM, DIC; any organ may be involved | 1-4 weeks, usually RD | Tropics worldwide | Inhalation of spores from soil; severe disease, usually IH |
| Leptospirosis (<i>Leptospira</i> spp.) | Icterus, jaundice, conjunctival suffusion, rash, HSM; may be biphasic; may develop hepatorenal syndrome, CNS involvement, or pulmonary disease with hemorrhage | 2-20 days | Worldwide | Contaminated urine of many types of small mammals, either directly or through soil or standing water; hunting; military exercises |
| Malaria (<i>Plasmodium falciparum</i> , <i>P. vivax</i> , <i>P. ovale</i> , <i>P. malariae</i> , and <i>P. knowlesi</i>) | See text | See Table 133-2 | See Fig. 133-1 and Table 133-2 | Mosquito bite; transfusion |
| Measles | Conjunctivitis, coryza, cough, rash, Koplik spots | 5-14 days | Worldwide | Person-to-person via aerosol |
| Melioidosis (<i>Burkholderia pseudomallei</i>) | May develop pneumonia or local suppurative infection, shock (especially if IH) | 2-21 days | Southeast Asia (especially Thailand), Australia, sporadic foci in tropics worldwide | Exposure to contaminated soil or infected animals, person-to-person (rare), often IH |
| Monkeypox (monkeypox virus) | Diffuse vesicular rash resembling chickenpox but involving palms and soles, lymphadenopathy | 3-21 days | Central and West Africa | Person-to-person as well as from exposure to infected small mammals and monkeys; exotic pets; rule out smallpox/bioterrorism |
| <i>Mycobacterium avium-intracellulare</i> , disseminated | Usually subacute, HSM, weight loss | Months-years | Worldwide | Environmental organism causing opportunistic infection in IH |
| Oroya fever (<i>Bartonella bacilliformis</i>) | Acute anemia, jaundice, HSM, lymphadenopathy | 2-3 weeks | Peru, Ecuador, Colombia | Sandfly bite; hiking, camping |
| Paracoccidioidomycosis (<i>Paracoccidioides brasiliensis</i>) | May involve lungs, bones, skin, lymph nodes, adrenal glands, or mucous membranes | 1-4 weeks, often RD | Tropical America | Inhalation of spores from soil; more severe in IH |
| Penicilliosis (<i>Penicillium marneffe</i>) | Mucocutaneous lesions, HSM, lymphadenopathy, may have skeletal or pulmonary involvement | Unknown, probably >1 week | Southeast Asia | Reservoir unknown, most often IH |
| Plague (<i>Yersinia pestis</i>) | Localized tender lymphadenitis ("bubo"), pneumonia, shock | 2-8 days | Worldwide | Flea bite or person-to-person; areas of heavy rat infestations, R/O bioterrorism |

Continued

TABLE 133-1 Some Tropical Diseases That May Merit Management in an Intensive Care Unit*—cont'd

| DISEASE AND ORGANISM | DISTINGUISHING CLINICAL FEATURES | INCUBATION PERIOD | GEOGRAPHIC DISTRIBUTION | MODE OF TRANSMISSION AND TYPICAL RISK FACTORS |
|---|---|--|--|--|
| Q fever (<i>Coxiella burnetii</i>) | HSM; may develop pneumonia, endocarditis, hepatitis, osteomyelitis, or neurologic abnormalities | 2-29 days | Worldwide | Inhalation of organism from products of infected livestock or pets, especially birth products but also milk, urine, and feces; farmers, ranchers |
| Rat bite fever (<i>Spirillum minor</i> or <i>Streptobacillus moniliformis</i>) | Peripheral rash, sometimes with desquamation, polyarthritides in <i>S. moniliformis</i> , eschar or ulcer at site of bite in <i>Spirillum minor</i> | 2-28 days | Worldwide, especially Asia and North America | Bite of rat or other animal that preys on rats; ingestion of food contaminated by rat |
| Relapsing fever (<i>Borrelia</i> spp.) | Recrudescence fever pattern, HSM, petechiae, epistaxis, neurologic abnormalities | 4-18 days | Worldwide (especially East Africa) | Body louse (<i>B. recurrentis</i>) or tick bite (various <i>Borrelia</i> species); conditions of poor hygiene, outdoor exposures, refugee camps, camping, safari |
| Rickettsiosis, spotted fever group (<i>Rickettsia rickettsii</i> , <i>R. conorii</i> , <i>R. africae</i> , <i>R. australis</i> , <i>R. sibirica</i> , <i>R. japonica</i> , <i>R. honei</i> , and <i>R. akari</i>) | Peripheral skin rash, eschar at site of tick bite may be seen ("tache noire"), may progress to GI, renal, pulmonary, or CNS involvement | 7-14 days | Worldwide (with circumscribed distributions of each specific organism) | Tick bite (mite for <i>R. akari</i>); camping, safari |
| Rickettsiosis, typhus group (<i>Rickettsia prowazekii</i> , <i>R. typhi</i> , and <i>R. felis</i>) | Centripetal rash (~50%), no eschar | 7-14 days | Worldwide, especially cold climates | Feces from infected louse (<i>R. prowazekii</i>) or flea (<i>R. typhi</i> and <i>R. felis</i>) rubbed into broken skin; crowding, poor hygiene, abundant rodents, refugee camps, and flea-infested cats |
| Scarlet fever (group A <i>Streptococcus pyogenes</i>) | Pharyngitis, "sandpaper" rash, cervical adenopathy | 1-4 days | Worldwide | Person-to-person via aerosolization/droplets |
| Schistosomiasis, Katayama fever (<i>Schistosoma</i> spp., especially <i>S. japonicum</i>) | Lymphadenopathy, HSM, eosinophilia | 1-2 months | Africa, Asia, Caribbean, Middle East, South America, Caribbean | Skin penetration of cercaria; swimming or bathing in contaminated water |
| Scrub typhus (<i>Orientia tsutsugamushi</i>) | Centripetal rash, conjunctival suffusion, lymphadenopathy, eschar at site of chigger bite (~50%), hearing loss in one-third of cases | 6-18 days | Asia, Australia, Pacific Islands | Chigger bite; outdoor rural or suburban exposures |
| Strongyloidiasis, disseminated (<i>Strongyloides stercoralis</i>) | Abdominal pain and distention, shock, pulmonary and CNS involvement common | 2-3 weeks; may be maintained via autoinfection for decades | Tropics worldwide | Skin contact with contaminated soil; military exercises; dissemination may occur in IH (AIDS, steroid treatment) |
| Toxic shock syndrome (<i>Staphylococcus aureus</i> , group A <i>S. pyogenes</i>) | Rash, extremity or abdominal pain, skin desquamation, soft-tissue infection (70%) | 2-10 days | Worldwide | Wound or vaginal colonization with toxin-producing bacteria; history of minor trauma (often without break in skin), previous surgery, or varicella infection; staphylococcal syndrome often associated with menses |
| Trench fever (<i>Bartonella quintana</i>) | Rash, HSM, shin pain; may develop endocarditis and angioma-like lesions | 1-2 weeks | Worldwide | Body louse bite; areas of crowding or poor sanitation, more severe in IH |
| Trichinellosis (<i>Trichinella</i> spp.) | Diarrhea followed by myalgias, periorbital edema, eosinophilia; may involve heart or CNS | 7-30 days | Worldwide | Ingestion of contaminated meat, including pork (<i>T. spiralis</i>), wild boar, horse, bear, and walrus |
| Tularemia, typhoidal form (<i>Francisella tularensis</i>) | Pulse-temperature dissociation, diarrhea (~40%); may develop pneumonia | 1-21 days | Sporadic foci worldwide, mostly Northern Hemisphere | Tick or fly bite or direct exposure to small mammals; hunting, camping, military exercises; R/O bioterrorism |
| Typhoid fever (<i>Salmonella typhi</i>) | Pulse-temperature dissociation, abdominal pain, rash, intestinal perforation and bleeding, HSM, 10% with extraintestinal manifestations | 8-28 days | Worldwide | Fecal-oral |
| Vibrio infection, nonepidemic type (<i>Vibrio vulnificus</i>) | Bullous skin lesions, DIC, thrombocytopenia, GI bleeding, shock | 1-2 days | Worldwide | Contaminated salt water or seafood; severe disease mostly in IH, history of alcoholism, liver disease |
| Viral hemorrhagic fever (dengue, yellow fever, Ebola, Marburg, Lassa, Junin, Machupo, and Rift Valley fever viruses, many others) | Capillary leak syndrome; may or may not exhibit frank hemorrhage, GI hemorrhage, shock | 3-21 days, depending on specific virus | Select areas worldwide | Depending on specific virus: exposure to rodent excreta, infected nonhuman primates, person-to-person, tick or mosquito bite, some unknown; R/O bioterrorism |

| DISEASE AND ORGANISM | DISTINGUISHING CLINICAL FEATURES | INCUBATION PERIOD | GEOGRAPHIC DISTRIBUTION | MODE OF TRANSMISSION AND TYPICAL RISK FACTORS |
|--|--|--|--|--|
| Viral hepatitis (hepatitis A, B, C, D, and E; Epstein-Barr virus; cytomegalovirus; others) | HSM, light-colored stools, dark urine, jaundice | 2 weeks-5 months, depending on specific organism | Worldwide | Fecal-oral or ingestion of seafood from contaminated sea beds (hepatitis A, E); percutaneous (blood exposure), sexual, or mother-to-child transmission (hepatitis B, C, D); hepatitis D requires co-infection with hepatitis B virus |
| Visceral leishmaniasis (<i>Leishmania</i> spp.) | Weight loss, HSM, neutropenia | Months-years | Tropics worldwide, especially Indian subcontinent, Middle East, and North Africa | Sandfly bite; military exercises, outdoor exposures |
| GASTROINTESTINAL SYNDROMES | | | | |
| Amoebic dysentery (<i>Entamoeba histolytica</i> , rarely other amoebae) | Abdominal pain and diarrhea, sometimes bloody, minority may develop amoeboma, toxic megacolon, peritonitis, or abscesses in solid organs (usually liver) | 2-4 weeks (usually longer for solid organ involvement) | Worldwide | Fecal-oral; may be transmitted through anal sex |
| Anthrax, gastrointestinal or oropharyngeal (<i>Bacillus anthracis</i>) | Abdominal pain and bloody diarrhea, neck swelling, pharyngitis, mucosal lesions, shock | 2-10 days | Worldwide | Ingestion of spores; exposure to domestic animals or animal byproducts; R/O bioterrorism |
| Ascending cholangitis (<i>Clonorchis sinensis</i> and <i>Opisthorchis</i> spp.) | May be recurrent and accompanied by pancreatitis | Months-years | Asia, former USSR | Ingestion of raw infected freshwater fish; sushi consumption |
| Bacterial dysentery (<i>Shigella</i> spp., <i>Campylobacter</i> spp., invasive and hemorrhagic <i>Escherichia coli</i> , non-typhi <i>Salmonella</i> spp., <i>Vibrio parahaemolyticus</i> , others) | Abdominal pain and diarrhea, sometimes bloody | 10 hours-7 days, depending on specific organism | Worldwide | Fecal-oral |
| Cholera (<i>V. cholerae</i>) | Copious "rice water" diarrhea, abdominal pain, severe hypovolemia, fever minimal or absent | 1-3 days | Tropics worldwide | Contaminated water or food, especially seafood; ceviche consumption |
| Clostridial gastroenteritis (<i>Clostridium difficile</i>) | Abdominal pain and diarrhea, sometimes with mucus or blood, toxic megacolon | ~1 week to months | Worldwide | Alteration of GI flora through previous antibiotic administration and/or GI manipulation |
| Eosinophilic gastroenteritis (<i>Angiostrongylus costaricensis</i>) | Mimics appendicitis or inflamed Meckel's diverticulum, right lower quadrant abdominal pain and mass, eosinophilia | Estimated 3-4 weeks | Latin America | Ingestion of larvae in undercooked mollusks, crustaceans, or frogs |
| Hemolytic uremic syndrome (<i>E. coli</i> O157:H7) | Bloody diarrhea followed by hemolysis and renal failure | 2-5 days | Worldwide | Ingestion of poorly cooked meat, fecal-oral |
| NEUROLOGIC SYNDROMES | | | | |
| African trypanosomiasis, meningoencephalitic stage (<i>Trypanosoma brucei gambiense</i> and <i>Trypanosoma brucei rhodesiense</i>) | Headache, HSM, cervical lymphadenopathy, somnolence, change in mental status, extrapyramidal and cerebellar signs | Months-years | Sub-Saharan Africa | Tsetse fly bite; camping, safari |
| Antiretroviral syndrome (human immunodeficiency virus-1) | Usually asymptomatic or mild flu-like illness, meningoencephalitis occurs rarely | 2-4 weeks | Worldwide | Sexual transmission or percutaneous blood exposure; unprotected sex, IV drug use |
| Arboviral encephalitides (eastern equine, Japanese encephalitis, West Nile, Murray Valley encephalitis, St. Louis encephalitis, and Venezuelan equine encephalitis viruses, many others) | Encephalitis, focal neurologic deficits, seizures, change in mental status | 3-21 days | Sporadic foci worldwide | Mosquito bite; seasonal |
| Bacterial meningitis (<i>Neisseria meningitidis</i> , <i>Streptococcus pneumoniae</i> , <i>Haemophilus influenzae</i> type B, <i>Listeria monocytogenes</i> , others) | Petechiae, ecchymoses, and bleeding suggest <i>N. meningitidis</i> | 2-10 days, depending on specific organism | Worldwide; <i>N. meningitidis</i> more frequent in African "meningitis belt" | Person-to-person, asymptomatic carrier states, seasonal fluctuations |
| Botulism (<i>Clostridium botulinum</i>) | Bilateral cranial nerve deficits with symmetric descending weakness, fever absent | 1-3 days | Worldwide | Toxin ingestion or wound contamination; home-canned foods, soil contamination |

TABLE 133-1 Some Tropical Diseases That May Merit Management in an Intensive Care Unit*—cont'd

| DISEASE AND ORGANISM | DISTINGUISHING CLINICAL FEATURES | INCUBATION PERIOD | GEOGRAPHIC DISTRIBUTION | MODE OF TRANSMISSION AND TYPICAL RISK FACTORS |
|---|---|---|--|--|
| Brain abscess (various bacteria, fungi, and parasites) | Focal neurologic signs | Days-months, depending on specific organism | Worldwide | Varies with infecting organism |
| Cryptococcosis (<i>Cryptococcus neoformans</i>) | Mild meningitis with low-grade fever, nonfocal neurologic exam, sometimes seizures or pulmonary involvement | 1-4 weeks | Worldwide | Inhalation of spores from soil and bird and bat excreta; usually IH |
| Eosinophilic meningitis (<i>Angiostrongylus cantonensis</i>) | Headache, meningitis, sometimes cranial nerve involvement, fever minimal | 1-7 days | Southeast Asia, South Pacific, sporadic foci worldwide | Ingestion of larvae in undercooked mollusks, crustaceans, or frogs |
| Gnathostomiasis (<i>Gnathostoma</i> spp.) | Migratory skin and subcutaneous swellings, epigastric pain and vomiting, eosinophilia, may invade any organ, especially CNS | Weeks-years | Southeast Asia, with sporadic cases from Central and South America | Consumption of raw freshwater fish, frogs, snakes, crustaceans, or poultry; sushi consumption |
| Herpes encephalitis (various herpesviruses) | Encephalitis, focal neurologic deficits, seizures, change in mental status, may show vesicular eruption | 2-20 days, depending on specific virus | Worldwide; herpes B virus via monkey exposure in Asia and North Africa (wild monkeys) or captive monkeys worldwide | Person-to-person, often more severe in IH; herpes B virus via bite or other exposure to monkeys of the genus <i>Macaca</i> ; person-to-person transmission reported; researchers, animal handlers |
| Mucormycosis (various fungi from the order Mucorales) | CNS infiltration with loss of consciousness, black exudate around mucous membranes of face, pulmonary infiltrates | 1-7 days | Worldwide | Inhalation of spores from soil, traumatic inoculation of wound; usually IH (diabetes mellitus or steroid use) |
| Neurocysticercosis (<i>Taenia solium</i>) | Seizures, headache, change in mental status, muscle pain | Years | Worldwide, especially Latin America and India | Ingestion of cysticerci in contaminated pork; areas where pigs roam freely |
| Paragonimiasis, cerebral (<i>Paragonimus</i> spp.) | Meningoencephalitis, often accompanied by pulmonary disease | Years | Sporadic foci worldwide, especially East Asia, Peru, Ecuador, and West Africa | Ingestion of raw infected crustaceans; sushi consumption |
| Poliomyelitis (poliovirus) | Acute flaccid paralysis, meningeal signs, muscle pain | 9-12 days | Sporadic foci in Africa, Asia, and eastern Mediterranean | Fecal-oral |
| Primary amebic meningoencephalitis (<i>Naegleria fowleri</i>) | Fulminant meningoencephalitis | 3-7 days | Sporadic foci worldwide | Entry of trophozoite through the nose; swimming in contaminated fresh warm water; hot springs |
| Rabies (rabies virus) | Change in mental status, autonomic instability, photophobia, aerophobia, paralysis | 20-90 days | Worldwide | Animal bite or bat exposure; spelunking, caring for injured animals |
| Schistosomiasis, CNS (<i>Schistosoma</i> spp.) | Encephalopathy, meningoencephalitis, transverse myelitis, seizures | Weeks-months | Africa, Asia, Caribbean, Middle East, South America, Caribbean | Skin penetration of cercaria; swimming or bathing in contaminated water |
| Tetanus (<i>Clostridium tetani</i>) | Diffuse muscle spasms, opisthotonos, trismus, autonomic dysfunction | 3-21 days | Worldwide | Soil contamination of wound, commonly involves umbilical stump in neonates |
| Tickborne encephalitis (tickborne encephalitis virus) | Encephalitis, focal neurologic deficits, seizures | 7-14 days | Central and East Asia, Europe, North Africa, North America | Tick bite |
| Toxoplasmosis, cerebral (<i>Toxoplasma gondii</i>) | Meningoencephalitis, HSM, focal neurologic deficits, seizures, change in mental status | Usually RD | Worldwide | Ingestion of cysts in undercooked meat or oocysts from exposure to cat feces; usually IH |
| Variant Creutzfeldt-Jacob disease (prion) | Change in mental status, myoclonus, spasticity, rigidity, extrapyramidal and cerebellar signs and symptoms, occasionally seizures | Months-years | United Kingdom, with sporadic cases elsewhere in Europe, Canada, and United States | Recipients of cadaveric transplants or injections of biomedical products derived from infected patients, contaminated surgical apparatuses, person-to-person(?), ingestion of contaminated beef or lamb(?) |
| Visceral larva migrans (<i>Toxocara canis</i>) | Cough, wheezing, HSM, eosinophilia; may develop CNS or other solid organ involvement | Weeks-years | Worldwide | Ingestion of eggs in puppy feces |

TABLE 133-1 Some Tropical Diseases That May Merit Management in an Intensive Care Unit*—cont'd

| DISEASE AND ORGANISM | DISTINGUISHING CLINICAL FEATURES | INCUBATION PERIOD | GEOGRAPHIC DISTRIBUTION | MODE OF TRANSMISSION AND TYPICAL RISK FACTORS |
|---|--|--|---|--|
| PULMONARY SYNDROMES | | | | |
| Anthrax, inhalation (<i>Bacillus anthracis</i>) | Pulmonary infiltrates with widened mediastinum, shock, CNS involvement | 2-60 days | Worldwide | Inhalation of spores, exposure to domestic animals or animal byproducts; R/O bioterrorism |
| Aspergillosis (<i>Aspergillus</i> spp.) | Pulmonary "fungus ball" (aspergilloma), transient infiltrates and allergic symptoms in allergic bronchopulmonary aspergillosis | 1-4 weeks | Worldwide | Inhalation of spores from soil |
| Bacterial pneumonia (<i>Streptococcus pneumoniae</i> , <i>Legionella pneumophila</i> , <i>Mycoplasma pneumoniae</i> , <i>Haemophilus influenzae</i> , <i>Chlamydia</i> spp., others) | Extrapulmonary findings frequent in Legionnaire's disease and psittacosis | 2-21 days, depending on specific organism | Worldwide | Person-to-person spread; Legionnaire's disease associated with colonized air/water systems; psittacosis associated with bird exposure |
| Blastomycosis (<i>Blastomyces dermatitidis</i>) | Subacute pneumonia; bone, skin, and GU tract involvement | 1-4 weeks, usually RD | Sporadic foci worldwide | Inhalation of spores from soil |
| Diphtheria (<i>Corynebacterium diphtheriae</i>) | Low-grade fever, cough, pharyngitis, oropharyngeal membrane, neck swelling, mucosal bleeding, myocarditis, polyneuritis | 3-7 days | Worldwide, especially temperate areas | Person-to-person through respiratory route and breaks in the skin |
| Eosinophilic pneumonia (various parasites, helminth, and filaria) | Eosinophilia, asthma-like condition, elevated IgE | Days-weeks, depending on specific organism | Worldwide, depending on specific organism | Lung passage of larvae or adult helminths, mosquito bite (filaria), filarial disease occurs primarily in those living in endemic areas with continued exposure |
| Hantavirus pulmonary syndrome (various hantaviruses) | ARDS, thrombocytopenia, leukocytosis, hemoconcentration, circulating immunoblasts | 1-5 weeks | Americas | Contaminated rodent urine or feces; outdoor exposures |
| Pertussis (<i>Bordetella pertussis</i>) | Low-grade fever, coryza, rhinorrhea, paroxysmal dry cough | 5-21 days | Worldwide | Person-to-person; adults vaccinated as children are susceptible to milder disease |
| Pneumocystosis (<i>Pneumocystis jiroveci</i>) | Dyspnea, dry cough, hypoxemia, often only mild findings on pulmonary auscultation and CXR | Usually RD | Worldwide | Inhalation; usually IH |
| Tuberculosis (<i>Mycobacterium tuberculosis</i>) | Upper lobe infiltrates and cavities; miliary TB, meningitis, and GU involvement also common | Usually RD | Worldwide | Person-to-person via aerosol/droplet; increased frequency and likelihood of extrapulmonary involvement in IH |
| Tularemia, pneumonic form (<i>F. tularensis</i>) | Pulse-temperature dissociation, diarrhea (~40%) | 1-21 days | Sporadic foci worldwide, mostly Northern Hemisphere | Tick or fly bite, or direct exposure to small mammals; hunting, camping, military exercises, R/O bioterrorism |
| Viral pneumonia (influenza, parainfluenza, respiratory syncytial, and SARS coronavirus, many others) | May be complicated by bacterial superinfection | Days-weeks, depending on specific organism | Worldwide, depending on specific organism | Person-to-person spread and zoonotic, depending on specific virus; contact with farms or live-animal markets, birds, or pigs (zoonotic influenzas); civet cats suspected to be a reservoir of SARS coronavirus |
| LOCALIZED INFECTIONS | | | | |
| Mycetoma (various fungi and bacteria) | Chronic swollen limb with nodules, sinus tracts, drainage of pus and "grains" | Weeks-months | Tropics worldwide | Traumatic implantation of organism into skin; soil exposure |
| Necrotizing fasciitis (group A <i>S. pyogenes</i> , <i>Clostridia</i> spp., <i>S. aureus</i>) | Rapid progression of edema, erythema, tenderness, bullae, necrosis, and gangrene | ~24 hours | Worldwide | Posttraumatic or surgical |

*Only diseases that typically have acute or subacute presentations and may cause severe disease are included. Diseases are classified by the most typical associated severe syndrome. In practice, significant variation may exist.

[†]Initial infection is usually asymptomatic or mild. Reactivation with severe disease may occur years later, usually in immunocompromised hosts.

ARDS, acute respiratory distress syndrome; CNS, central nervous system; CXR, chest x-ray; DIC, disseminated intravascular coagulopathy; GI, gastrointestinal; GU, genitourinary; HSM, hepatosplenomegaly; IgE, immunoglobulin E; IH, immunocompromised host; IV, intravenous; RD, reactivation disease; R/O, rule out; TB, tuberculosis; SARS, severe acute respiratory syndrome.

on parasitized RBC membranes that mediate their adhesion to the venular endothelium (Fig. 133-2). The rupture of schizont-stage parasites exposes glycosylphosphatidylinositol anchors on the parasite and RBC surface that induce macrophages and other inflammatory cells to release a host of inflammatory mediators including tumor necrosis factors (TNF), interleukin-1, and various kinins and reactive nitrogen intermediates.²⁵⁻²⁷ These cytokines play a role in the upregulation and

activation of endothelial adhesion molecules, such as ICAM-1 and E-selectin, enhancing cytoadherence of parasitized cells and mediating pathologic processes such as hypoglycemia, lactic acidemia, shock, gut mucosal damage, and increased permeability and neutrophil aggregation in the lung. The sum total of this cascade is sequestration of parasitized RBCs in the microvasculature where they are not only sheltered from removal but cause sluggish flow and obstruction, resulting in

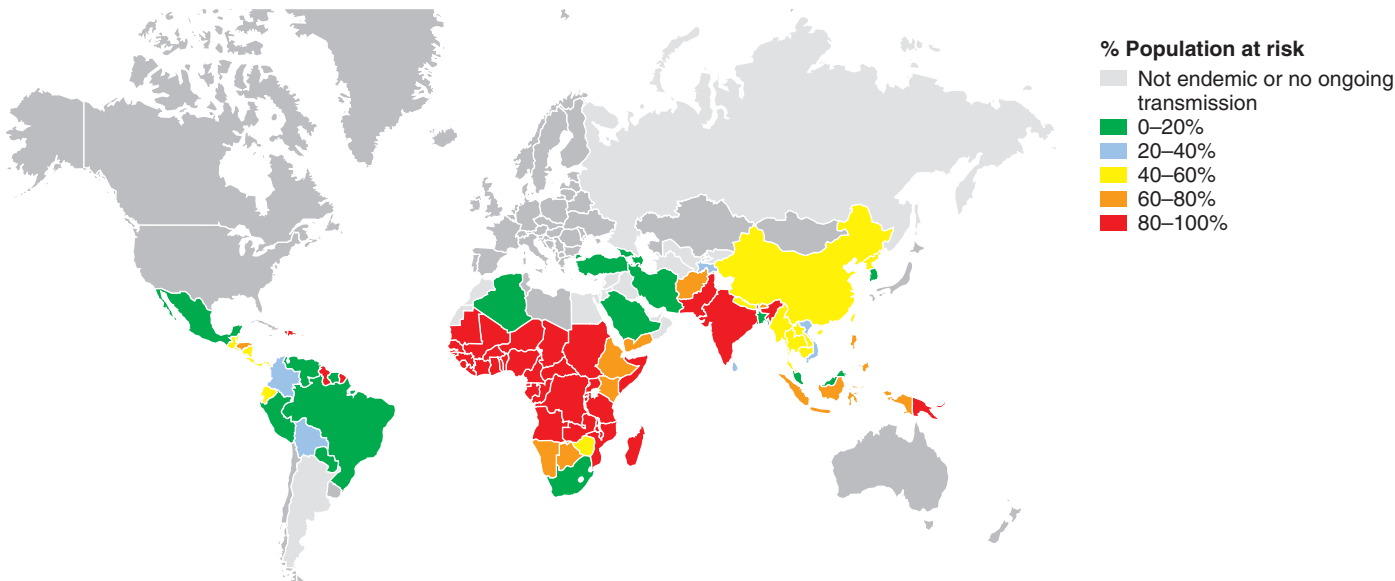

FIGURE 133-1 ■ Population at risk in malaria-endemic countries in the Western and Eastern hemispheres. The risk of malaria may vary within specific regions of each country. (From the World Health Organization 2013. Available at: <http://worldmalariaeurope.org>.)

TABLE 133-2 Features of the Five Species of Malaria Known to Cause Disease in Humans

| | PLASMODIUM FALCIPARUM | PLASMODIUM VIVAX | PLASMODIUM OVALE | PLASMODIUM MALARIAE | PLASMODIUM KNOWLESI |
|-----------------------------------|---|--|--|---|--|
| Incubation period (day) | 6-25 | 8-27 | 8-27 | 16-40 | 12 |
| Asexual cycle (hour) | 48 (tertian) | 48 (tertian) | 48 (tertian) | 72 (quartan) | 24 (tertian) |
| Relapse | No | Yes* | Yes* | No† | No |
| Chloroquine resistance | Yes‡ | Rare§ | No | No¶ | No |
| Characteristic on thin blood film | Rings predominate, multiply infected RBCs, high parasitemia, rings with thread-like cytoplasm, double nuclei, banana-shaped gametocytes | Enlarged RBCs, Schüffner's dots, trophozoite cytoplasm amoeboid, 12-24 merozoites in mature schizont | Oval RBCs with fringed edges, Schüffner's dots, trophozoites cytoplasm compact, 6-16 merozoites in mature schizont | Trophozoite cytoplasm compact (band forms), 6-12 merozoites in mature schizont, RBC unchanged | Similar to <i>P. malariae</i> , 8-10 merozoites in mature schizont, often in rosette pattern with central clump of pigment |

*Relapses may appear months to years after initial infection due to dormant hypnozoites in the liver.
†Although relapse does not occur, *P. malariae* can produce persistent infections that remain below detectable limits in the blood for 20 to 30 years or more.
‡*P. falciparum* resistance to sulfadoxine/pyrimethamine, mefloquine, halofantrine, and artemisinin has also been reported in some areas, along with partial resistance to quinine and quinidine.¹²⁸⁻¹³⁰
§*P. vivax* resistance to chloroquine has been reported in some areas of Southeast Asia, Oceania [Ethiopia, Madagascar], and South America.^{131-142,143}
¶Chloroquine-resistant *P. malariae* has also been reported in south Sumatra, Indonesia.¹⁴⁴
RBC, red blood cell.

impaired oxygen delivery and organ dysfunction.^{25,28} The most profound effects are usually on the cerebral capillaries, although a host of tissues may be affected, including the kidney, liver, spleen, placenta, intestine, lung, bone marrow, heart, and retina. Histopathologic changes are usually minimal, but ring hemorrhages and perivascular infiltrates sometimes develop at the sites of obstructed vessels, perhaps facilitated by thrombocytopenia because of splenic sequestration of platelets. Although subendocardial and epicardial hemorrhages have been noted at autopsy, myocarditis does not occur, and primary cardiac events are relatively rare in malaria.

However, in *P. vivax* infection, a very strong predilection for reticulocytes and the lack of cytoadhesive properties of the infected cells result in lower parasitemia and reduced microvascular obstruction and suggest different pathogenetic mechanisms to severe infection. A returning traveler exposed to *P. vivax* for a short period will rarely present a severe or fatal infection unless there is an underlying condition. However, in endemic regions, children with prolonged vivax infection due to frequent exposures and relapsing infections from the liver hypnozoites will present with profound anemia with subsequent high morbidity and mortality, particularly in the presence of

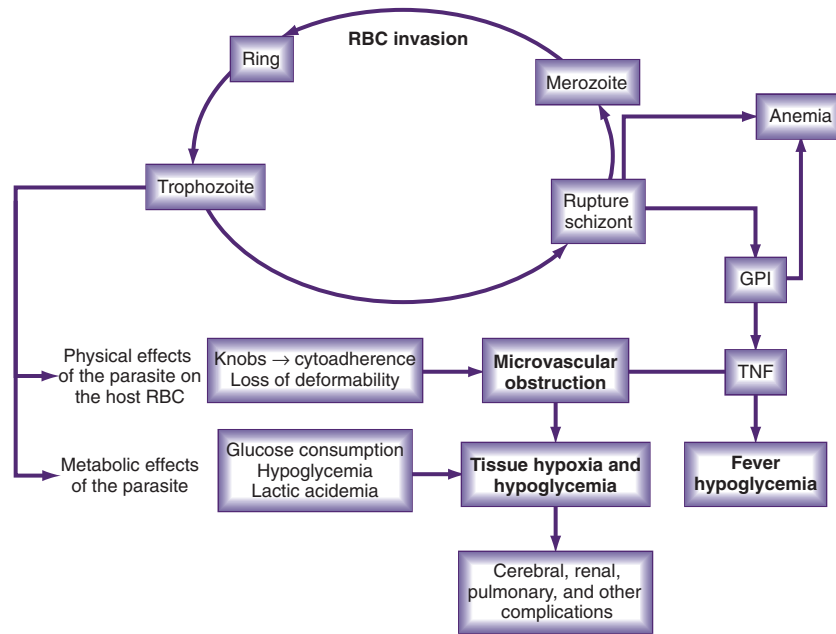

FIGURE 133-2 ■ Pathogenesis of severe and complicated *P. falciparum* malaria. GPI, glycosylphosphatidylinositol; RBC, red blood cell; TNF, tumor necrosis factor. (Modified from Krogstad D. Plasmodium species (malaria). In: Mandell GL, Bennett JE, Dolin R, editors. Principles and practice of infectious diseases. 5th ed. Philadelphia: Churchill Livingstone; 2000.)

malnutrition and other causes of anemia.²⁹ Vivax anemia is further deepened by the splenic high removal rate of uninfected RBCs, although the removal mechanism is not fully understood.^{17,30}

CLINICAL PRESENTATION

Malaria infections are broadly classified into three clinical categories: (1) *asymptomatic parasitemia*, which generally does not require treatment for those living in endemic areas; (2) *uncomplicated malaria*, defined as parasitemia and fever without evidence of end organ damage or other signs of severe disease (these patients may often be treated as outpatients with oral antimalarials); and (3) *severe and complicated malaria*, defined as parasitemia and the presence of vital organ damage or other signs of severe disease. Patients with severe and complicated malaria require hospitalization, often in an intensive care unit (ICU), and parenteral antimalarials. This third category is the focus of this chapter.

Malaria classically produces three stages of symptoms, which progress over an 8- to 12-hour period, comprising a “paroxysm.” These correspond and are attributable to the period of schizont rupture and appearance of ring forms (merozoites) in the blood, accompanied by the release of numerous host inflammatory mediators. The paroxysm classically begins suddenly with a “cold stage” in which the patient experiences rigors and chills, often accompanied by headache, nausea, and vomiting. Intense peripheral vasoconstriction may result in pale, goose-pimpled skin and cyanosis of the lips and nail beds. Within a few hours, the “hot stage” ensues, with high fever, flushed skin, throbbing headache, and palpitations. The paroxysm concludes with the “defervescent stage,” consisting of a drenching sweat and resolution of the fever. The exhausted patient often then sleeps. Clinical deterioration with *P. falciparum* usually appears 3 to 7 days after the onset of fever.

Although a classic periodicity is described for different malarial species (see Table 133-2), this occurs only when the infection has persisted untreated long enough to allow for synchronization of schizont rupture. Furthermore, schizont rupture tends to be asynchronous in *P. falciparum* and in most primary infections of any *Plasmodium*

species. Therefore, malaria may often result in persistent spiking fevers, difficult to distinguish from fevers produced by many other infections. The absence of a classic paroxysm and periodicity should not be used to exclude the diagnosis. Paroxysms may be accompanied by cough, sore throat, myalgias, back pain, postural hypotension, abdominal pain, nausea, vomiting, diarrhea, and weakness. These are more common in children and may lead to misdiagnoses. Rash and lymphadenopathy are not typical of malaria and require another diagnosis.

Severe and Complicated Malaria

Although all species of malaria may produce severe consequences in a debilitated patient, potentially fatal malaria that merits attention in an ICU can be grouped into three categories: (1) severe complications of *P. falciparum*, and less commonly *P. vivax* and *P. knowlesi* in nonimmune children and adults, responsible for the vast majority of severe diseases worldwide (Table 133-3); (2) splenic rupture, which occurs most frequently with *P. vivax*; and (3) chronic nephrotic syndrome due to immune-complex nephritis associated with *P. malariae*, usually seen in children and often complicated by overwhelming bacterial infection.

Cerebral Malaria

This is the most frequent severe complication of *Plasmodium* infection, accounting for most fatalities and chronic sequelae. It is most frequent in children of 3 to 5 years of age. Strictly defined, *cerebral malaria* implies unarousable coma due to *P. falciparum*.^{31,32} Hyperpyrexia and febrile convulsions in young children may produce transiently altered mental status without true involvement of the cerebral microvasculature and thus technically do not constitute cerebral malaria. However, in clinical practice, seizures or persistent changes in sensorium that cannot be attributed to other disease processes should be considered cerebral malaria until proven otherwise. Although cerebral malaria is classically attributed to cytoadhesion and microvascular obstruction in

TABLE 133-3

Clinical and Laboratory Features That Classify a Patient as Suffering from Severe *Plasmodium falciparum* Malaria* According to the World Health Organization

CLINICAL FEATURES

Impaired consciousness (including unarousable coma); Glasgow coma score <11 in adults or a Bantyre coma score <3 in children
 Prostration: generalized weakness so that the patient is unable walk or sit up without assistance
 Multiple convulsions (more than two episodes in 24 hours)
 Pulmonary edema: radiologic evidence or oxygen saturation <92% on room air with a respiratory rate >30/min
 Respiratory distress (severe acidosis): rapid, deep, labored breathing
 Circulatory collapse or shock, systolic blood pressure <80 mm Hg in adults and <70 mm Hg in children, with evidence of impaired perfusion (cool peripheries or prolonged capillary refill)
 Clinical jaundice plus evidence of other vital organ dysfunction
 Abnormal spontaneous and significant bleeding

LABORATORY FINDINGS

Hypoglycemia (blood glucose <2.2 mmol/L or <40 mg/dL)
 Metabolic acidosis; base deficit of >8 mEq/L, plasma bicarbonate <15 mmol/L or venous plasma lactate >5 mmol/L
 Severe normocytic anemia (hemoglobin ≤5 g/dL, hematocrit ≤15% in children <12 years of age (<7 g/dL and <20%, respectively, in adults) with a parasite count >10,000/μL
 Jaundice: plasma or serum bilirubin >50 μmol/L (3 mg/dL) with a parasite count >100,000/μL
 Hyperparasitemia: >10%
 Renal impairment: serum creatinine >265 μmol/L (3 mg/dL) or blood urea >20 mmol/L

Modified from Guidelines for the treatment of malaria 2015.3rd ed. Geneva: World Health Organization; 2010. Available at: <http://www.who.int/malaria/publications/atoz/9789241549127/en/>

*Comment:

For severe *P. vivax* malaria, the same criteria are used as for *P. falciparum* malaria but with no parasite density thresholds.

Likewise, severe *P. knowlesi* malaria is defined as for *P. falciparum* malaria but with two differences:

- *P. knowlesi* hyperparasitemia: parasite count >100,000/μL
- Jaundice and parasite count: >20,000/μL

(From the World Health Organization. Management of severe malaria—a practical handbook. 3rd ed. April 2013. Available at: <http://www.who.int/malaria/publications/atoz/9789241548526/en/>.)

the brain, other ongoing processes including hypoglycemia, metabolic acidosis, and impaired oxygenation due to anemia and pulmonary edema likely contribute.

The altered sensorium of cerebral malaria may develop gradually within a few days of onset of illness or manifest as persistent coma after a generalized convulsion. Compared with adults, children with cerebral malaria have a shorter history of fever before progressing to coma (average about 2 days). The most common neurologic picture is of a diffuse symmetric encephalopathy with hypertonia, opisthotonos, hyperreflexia, clonus, disconjugate gaze, absent abdominal reflexes, and extensor Babinski responses, sometimes with signs of frontal lobe release such as a pout reflex or bruxism. Hypotonia and acute cerebellar ataxia are sometimes seen as well, especially in India and Sri Lanka. Pupils are usually symmetric with intact pupillary, corneal, oculocephalic, and oculovestibular reflexes. There is usually no grasp reflex, and the gag reflex is normally maintained. Both decorticate and decerebrate posturing may occur.³² Nystagmus and a sixth nerve palsy have been noted, but papilledema and photophobia are almost never seen.³³

Convulsions may occur in up to 50% of cases of cerebral malaria. As a child ages above 3 to 4 years, seizures become more likely to represent cerebral malaria than febrile convulsions.³⁴ Although

generalized seizures are classically reported, partial motor seizures, with or without secondary generalization, may occur.³¹ Although often showing only diffuse cortical dysfunction, EEG studies may sometimes reveal underlying status epilepticus even when it is not clinically evident.³²

Pulmonary Edema and Acute Respiratory Distress Syndrome

Pulmonary edema, which may progress to acute lung injury (ALI) and acute respiratory distress syndrome (ARDS), is a frequent and typically the most lethal complication of malaria. It has been seen with infection by all malaria species.³⁴ In *P. falciparum* infection, evidence suggests that the mechanism may involve acute pulmonary hypertension precipitated by nitric oxide (NO) consumption by free plasma hemoglobin released from intravascular hemolysis.³⁵ Endothelial injury leading to increased alveolar permeability and noncardiogenic pulmonary edema may also contribute. Interstitial edema and inflammatory cell infiltrates are seen at autopsy, but sequestration of parasitized RBCs in the lung is uncommon.³⁶ Pulmonary complications occur in 5% to 30% of patients with severe malaria, especially pregnant women, nonimmune persons, and patients already suffering from other complications.³⁶ The onset may be any time during the course of illness, even if the patient appears to be improving and parasitemia has decreased. Symptoms include dyspnea and cough, with rapid progression to hypoxia and respiratory distress. In *P. vivax* infection, a cytokine-mediated inflammatory response in the pulmonary microvessels leads to increased alveolar permeability and fluid buildup. Because of a lower parasitic biomass, the effect of the hemolysis-associated NO depletion on pulmonary pressures is minimal.²⁹

Anemia and Hematologic Perturbations

Although some degree of anemia is common in all types of malarias, severe anemia (hemoglobin less than 5 g/100 mL) occurs mostly with *P. falciparum* owing to its high parasitemia and with *P. vivax*. In *P. falciparum* infection, severe anemia is most common and often severe in pregnant women and young children (<1 year), in whom it may be the presenting sign.³⁷ In addition to the acute hemolytic destruction of parasitized RBCs, the more chronic processes of removal of parasitized cells from circulation by the spleen and cytokine inhibition of erythropoiesis may contribute.³⁸ Nonimmune subjects may develop anemia within days after infection, whereas anemia usually develops more slowly in those who are semi-immune. The degree of anemia generally correlates with bilirubin level and level of parasitemia. It may be exacerbated by underlying glucose-6-phosphate dehydrogenase (G6PD) deficiency in the setting of administration of oxidant antimalarial drugs (e.g., quinine, sulfadoxine) and iron-deficiency anemia due to malnutrition. Significant jaundice and hemoglobinuria may result. Thrombocytopenia, although frequent, is not usually associated with bleeding or correlated with disease severity. Disseminated intravascular coagulation (DIC) is seen in less than 10% of severe cases. In *P. vivax* infection, profound anemia is seen in young children from high endemic areas and results from several pathogenetic processes including frequent hemolysis due to relapsing infection, increased fragility of infected and uninfected reticulocytes, high splenic removal rate of uninfected RBCs (four times higher than in *P. falciparum*), and recrudescence of chloroquine-resistant parasites.³⁰

Acute Kidney Injury

Acute kidney injury (AKI) is seen in about 30% of nonimmune adult patients with cerebral malaria but is uncommon in children. For unclear reasons, AKI is rare in semi-immune persons. AKI occurs mainly with *P. falciparum*, but it is also described with *P. vivax* and *P. malariae* and is generally a sign of poor prognosis.^{34,39} AKI is usually due to acute tubular necrosis, is oliguric in nature (<400 mL urine/24 h for adults), and is most often reversible. Renal ischemia due to

hypovolemia, renal vasoconstriction, microvascular obstruction, and pigment nephropathy from hemolysis may all contribute. Electrolyte abnormalities such as hyponatremia, hypocalcemia (usually related to albumin loss), hypophosphatemia, and metabolic acidemia, as well as fluid overload with pulmonary edema, may result.

Blackwater fever refers to a severe syndrome characterized by low or absent parasitemia, intravascular hemolysis, hemoglobinuria, and AKI. It is classically seen in people of northern European descent chronically exposed to *P. falciparum* and irregularly taking quinoline antimalarial drugs, quinine or quinidine, which together are known as *cinchona alkaloids*. The syndrome virtually disappeared after 1950 when chloroquine superseded quinine. However, it is now said to be resurgent, albeit with lower mortality, in relation to mounting chloroquine resistance and consequent increased use of quinine and the newer quinolines, such as mefloquine.⁴⁰

Hypoglycemia, Lactic Acidosis, and Other Metabolic Perturbations

Severe metabolic derangements are frequent, especially in pregnant women and young children. While sometimes asymptomatic in pregnancy, hypoglycemia (blood or plasma glucose <2.2 mmol/L) often causes convulsions and impaired consciousness and may be confused with cerebral malaria. Although the pathogenesis is still unclear, direct glucose consumption by the malaria parasite and cytokine inhibition of gluconeogenesis seem to be the main mechanisms. Decreased oral intake, depletion of liver glycogen, and insulin release stimulated by quinine or quinidine may also contribute.⁴¹ A meta-analysis showed hypoglycemia to be less frequent with artesunate treatment compared with quinine.⁴² Serum insulin levels are low, and lactate, alanine, and counterregulatory hormones are appropriately elevated. Although rarely clinically significant, mild hepatocellular damage may occur and be manifested by elevated hepatic transaminases and jaundice. At least theoretically, such hepatic dysfunction could result in impaired metabolic clearance of antimalarial medications and lactate and deficits in the production of coagulation factors and albumin.

Shock and Bacterial and Other Suprainfection

So-called *algid malaria*, referring to hypotension and shock, may resemble and indeed sometimes occur due to gram-negative sepsis from impaired flow in intestinal capillaries, with resultant mucosal erosion. Nontyphoidal salmonella septicemia is specifically associated with *P. falciparum*.⁴³ *Algid malaria* is often seen in the setting of hyperparasitemia, with concomitant hypoglycemia and lactic acidemia, and may progress to multiorgan system failure and death. As with most malarial complications, severe hemodynamic derangements are most often seen in nonimmune persons.⁴⁴ Whether bacteria are isolated or not, a classic septic shock picture is typical, with elevated cardiac index and decreased systemic vascular resistance.⁴⁵ Hemodynamic decompensation due to splenic rupture may mimic *algid malaria*.

A host of other infectious complications, including aspiration pneumonia and parvovirus infection, may be related to *falciparum* malaria. Malaria occurs with increasing frequency and severity in those who are HIV infected, especially during pregnancy, and can also transiently upregulate HIV replication.⁴⁶⁻⁵⁰ An association between severe malaria infection and hepatitis B surface antigen carriage has also been noted.⁵¹

Tropical Splenomegaly and Splenic Rupture

Splenomegaly is common in infection with all species of malaria. The *tropical splenomegaly syndrome*, also sometimes termed *hyperreactive malarial syndrome*, refers to a condition of massive splenomegaly, high titers of total serum immunoglobulin M and malaria-specific antibodies, and scanty or absent parasitemia. It is seen in individuals with a history of residence in an endemic area and can be associated with any malarial species. Host genetic factors appear to play a role.⁵²

Unlike virtually all the other complications of malaria that are most often associated with *P. falciparum*, acute splenic complications occur most commonly in *P. vivax*, especially with the first infection. Although the term *spontaneous splenic rupture* has traditionally been used, in reality a range of hematomas or tears of varying severity may occur. The rupture or tear usually occurs 2 to 3 months after infection, presumably as a result of increased intrasplenic tension, often precipitated by trauma of varying degrees or mechanical ventilation.⁵³ Over-eager examiners have been suggested to play a role, although no cases of clear palpation-induced rupture have been reported. Fever, tachycardia, vomiting, prostration, abdominal pain or guarding, tender splenomegaly, hypovolemia, and rapidly worsening anemia are common presenting features. Abdominal pain may be localized or diffuse, mild or severe. Shock may ensue. Diaphragmatic irritation after rupture may cause referred pain to the left shoulder, supraclavicular, or scapular regions ("Kehr's sign"). This is present in about one-half of cases and is said to have good specificity for rupture.

Malaria in Pregnancy and Children

Malaria is particularly dangerous in pregnant women and their fetuses are more susceptible to severe malaria with increased risk of pulmonary edema, hypoglycemia, severe anemia, infection premature delivery, low birth weight, and maternal and fetal death. Malarial parasites can often be found in the placenta and may impair oxygen and nutrient transport to the fetus. Disease is most severe in primiparae, especially if nonimmune. In contrast, women from endemic areas are usually asymptomatic, with the exception of the effects of anemia, again more severe in primiparae. Congenital malaria is rare except in infants born to nonimmune mothers.⁵⁴

DIAGNOSIS

Clinical

Malaria often presents with nonspecific signs and symptoms, so making a clinical diagnosis may be difficult. Although almost all patients have a history of fever, they may frequently be afebrile at the time of examination.⁵⁵ Physicians in industrialized countries who are unfamiliar with the disease may not initially include malaria in the differential diagnosis. Delayed diagnosis is frequent and associated with a poor outcome.^{6,56} Most patients with malaria will present within 1 month of exposure (See Table 133-2). Longer incubation periods may be seen in semi-immune persons or in those who have taken partial or inappropriate chemoprophylaxis. *P. vivax* and *P. ovale* infections can manifest later after months or even years after initial infection because of reactivation of liver hypnozoites.⁵⁷ The differential diagnosis includes most febrile illnesses found in the tropics (see Table 133-1). Babesiosis may present both clinically and microscopically similar to malaria in patients without travel to malaria-endemic areas. Cerebral malaria must be distinguished from bacterial meningitis, viral meningoencephalitis, metabolic coma, and intoxications by lumbar puncture.⁵⁸ In cerebral malaria, the cerebrospinal fluid (CSF) opening pressure is usually normal, although a few lymphocytes and moderate elevation of protein may be seen. High CSF lactate and low glucose indicate a poor prognosis.

Conventional Microscopy

Laboratory diagnosis has traditionally been made via the examination of thick and thin Giemsa-stained smears by light microscopy. This remains the standard method for diagnosing malaria. Thick smears are more sensitive in diagnosing malaria, whereas thin smears allow the identification of the specific parasite. Either smear can be used to quantify the level of parasitemia, but thick smears are theoretically more sensitive for this purpose.^{59,60} In addition to diagnosis, parasite quantification, and species identification, microscopy allows the monitoring of response to treatment (i.e., decreased parasitemia) and the

disease severity (i.e., presence of schizonts in *P. falciparum* infection).^{61,62} Simultaneous infections with multiple strains of *P. falciparum* are common in some areas of sub-Saharan Africa and also may occur with *P. vivax* in Southeast Asia and Latin America.^{63,64} Blood obtained by pricking a fingertip or earlobe is preferred because parasite densities are higher in these capillary-rich areas, although blood obtained by venipuncture collected in heparin or EDTA anticoagulant-coated tubes is acceptable if used shortly after being drawn (to prevent alteration in the morphology of white blood cells and malarial parasites).⁶⁵ Smears should be taken as soon as the diagnosis of malaria is considered, without waiting for manifestation of a classic paroxysm. Parasitemia may be undetectable in the early stages of the illness, in those with partial immunity, and in those who have previously self-administered antimalarials, a common practice in malaria-endemic areas.⁶⁶ Levels of parasitemia may fluctuate over time, necessitating repeated smears for diagnosis. Furthermore, *P. falciparum*-parasitized RBCs may be sequestered in the deep capillaries of the spleen, liver, and bone marrow. Although a blood film is unlikely to be falsely negative in a patient with severe disease, negative smears should not prevent prompt administration of antimalarial therapy if the diagnosis is strongly suspected.¹⁵ Conversely, asymptomatic parasitemia is common in children from endemic areas, and thus a positive smear does not necessarily signify a clinical case under these circumstances.

Considerable expertise at reading malarial smears may be necessary to detect and distinguish the parasites (see Table 133-2). *P. knowlesi* may often be misdiagnosed as *P. falciparum* or *P. malariae* owing to similar morphology. Superimposed platelets, particles of stain, pits in the slide, RBC inclusions such as Howell-Jolly bodies and those seen in siderocytes, and other intracellular pathogens such as *Bartonella* and *Babesia* must be distinguished from malarial parasites. Furthermore, alterations in parasite morphology may occur related to strain variation, drug pressure, and blood collection method.

Newer Laboratory Methods

Various new diagnostic techniques for malaria have been developed, including microscopy with fluorescent stains, dipstick antigen detection (i.e., rapid diagnostic test, RDT), DNA probes, polymerase chain reaction (PCR) assays, and automated blood cell analysis.^{59,60,67-71} Use of one of these new diagnostic modalities should be considered when a high suspicion of malaria remains despite repeatedly negative blood smears, especially if the microscopist has limited experience in reading malarial smears.⁶⁰ Each technique has unique advantages and disadvantages, but the sensitivity and specificity for *P. falciparum* is generally similar or better than conventional microscopy. Because of its greater sensitivity (as low as 5 parasites/ μ L), PCR may be a particularly valuable tool in nonimmune persons. PCR also allows evaluation for possible infection with multiple malarial strains and determination of drug resistance. A large number of malaria RDTs have been approved for use. RDTs are fast (usually with a result in less than 30 minutes) and easy to perform with sensitivities and specificities comparable to microscopy for *P. falciparum*. Sensitivity and specificity are lower for *P. vivax* and when the parasitemia is less than 100 parasites/ μ L, regardless of the species. RDTs based on the detection of the plasmodial lactate dehydrogenase antigen can be used to determine the efficacy of drug therapy since this antigen disappears rapidly after parasite clearance relative to other antigens detected by RDTs. False-negative malaria RDT results may occur because of a prozone-like-effect in high parasitemias.

RDTs cannot detect *P. knowlesi*-specific antigen, and cross-reaction with *P. falciparum* and *P. vivax* lactate dehydrogenase (pLDH) antibodies has been described. Microscopy is also not ideal, as *P. knowlesi* is often misdiagnosed as *P. malariae* or *P. falciparum* because of similar morphology.⁷²

Imaging

Computed tomography (CT) or magnetic resonance imaging (MRI) scanning of the abdomen is the usual diagnostic modality when splenic

rupture is considered, although ultrasonography, arteriography, bleeding scans, or exploratory laparotomy may sometimes be needed. Findings such as increased brain volume and, occasionally, brain swelling have been noted in CT and MRI studies in cerebral malaria, but these tests are generally unhelpful clinically and are indicated only to rule out suspected mass lesions when the diagnosis of cerebral malaria is uncertain.⁷³

CLINICAL MANAGEMENT

Indications for Admission to the Intensive Care Unit and General Management

Features that indicate severe disease meriting admission to an ICU and urgent intravenous (IV) therapy are noted in Table 133-3. In these critically ill patients, chloroquine-resistant *P. falciparum* should be assumed until proven otherwise. As per routine ICU management, the patient's breathing and circulatory status should first be rapidly assessed, the airway secured, and the neurologic status scored on the Glasgow Coma Scale or other appropriate scoring system.⁷⁴ For patients in profound shock, blood cultures should be drawn and broad-spectrum antibiotics begun unless the diagnosis of severe malaria has already been confirmed or if bacterial suprainfection is suspected. Unconscious patients should have a lumbar puncture to rule out bacterial meningitis.

Careful attention to fluid balance is imperative, especially considering the very poor prognosis once pulmonary edema or ARDS develops. Measurements of urine output and daily weights should be routinely performed. Monitoring of central venous pressure should be considered in critically ill patients. In patients with shock, initial effective fluid resuscitation with frequent monitoring, assessment of concomitant bacterial infection, and vasopressor support when required is the standard of care and should be initiated promptly. In patients with stable blood pressure and cardiac output, careful maintenance fluid therapy with regular assessment of tissue perfusion as therapeutic endpoints seems to be more beneficial than liberal fluid resuscitation to prevent the risk of capillary leak and acute pulmonary edema.⁷⁵

Hemofiltration or hemodialysis or peritoneal dialysis are indicated for AKI and may aid not only through improved fluid and electrolyte balance and control of acidemia but also via removal of circulating cytokine mediators of inflammation.⁷⁴ Although observations are limited, the quinolones appear not to be dialyzed.⁷⁷ Cautious transfusion of packed cells is usually indicated when the hematocrit falls below 20% or hemoglobin is less than 7 g/dL. In addition to improved oxygen transport, blood transfusion may reduce the parasite load and cytokine mediators of inflammation.^{55,78} Concurrent administration of diuretics may be warranted to avoid fluid overload. Use of low-dose dopamine and epinephrine has not been associated with significant improvement in renal oxygen metabolism or function.⁷⁹

Increasing respiratory distress may indicate the onset of ALI or ARDS. Arterial blood gas measurements may reveal hypoxemia, and chest x-rays bilateral infiltrates. Supplemental oxygen and mechanical ventilation may be required. In accordance with the National Institutes of Health ARDS Network Trial, lung-protective ventilation, with tidal volume of 6 mL/kg predicted body weight and plateau pressures less than 30 cm H₂O are indicated for improved survival.³⁶ Extracorporeal oxygenation has also been employed.⁸⁰ Metabolic acidosis should be treated by improving pulmonary gas exchange, correcting hypovolemia and hypoglycemia, and treating associated septicemia. Careful monitoring of serum potassium with appropriate supplementation is warranted, especially when correcting acidosis. Blood glucose should be checked frequently, especially in pregnant patients, and 50% dextrose administered when needed. Results of studies on the efficacy of continuous IV infusion of 5% dextrose have been mixed.^{81,82} Quinoline-induced hypoglycemia may be prevented by administering somatostatin analogs followed by glucagons.⁸³ Acute seizures may be treated with IV benzodiazepines or intramuscular (IM) paraldehyde, and prolonged seizures terminated with phenytoin.³² However, prophylactic

anticonvulsants with phenobarbital are not recommended and may be harmful.⁷⁵ Although the risk of bleeding is low, aspirin should be avoided in the presence of thrombocytopenia. Many patients with splenic rupture can be managed conservatively with supportive therapy, although splenectomy may be necessary.⁵²

In late pregnancy, fetal monitoring should be begun prior to initiation of quinoline therapy so that the effects of the disease can be distinguished from those of drug toxicity. Early obstetric intervention should be considered for the benefit of both mother and fetus. Although fetal distress is usually the result of placental insufficiency, it may sometimes be related to high maternal temperature and hypoglycemia. Thus these parameters should be carefully monitored and treated accordingly. Fluid balance is particularly crucial in pregnant patients; the sudden increase in peripheral vascular resistance postpartum may precipitate pulmonary edema. In young children prone to febrile convulsions, extra efforts should be made to control fever by the use of acetaminophen, cooling blankets, and baths.

Antimalarial Chemotherapy

Because delay of therapy is associated with increased mortality, empirical parenteral treatment should be implemented immediately in all suspected cases of severe malaria after obtaining appropriate blood specimens. Infection with chloroquine-resistant *P. falciparum* should be assumed unless specifically ruled out. Treatment regimens for severe *P. falciparum* are also effective for the more infrequent cases of severe malaria due to other species.

Two classes of medicines are indicated for parenteral treatment: artemisinin derivatives (artesunate, artemether, and others) and cinchona alkaloids (Table 133-4). Two large randomized trials showed artesunate to be superior to quinine for severe malaria in both adults and children.^{75,84,85,86} Intravenous or IM artesunate is the first-line drug recommended by the World Health Organization (WHO) for severe malaria and should be administered for at least 24 hours even if there is early improvement. If IV or IM artesunate is not available, IM artemether should be considered. After 24 hours, if patients are able to tolerate oral therapy, they may be transitioned to one of three recommended artemisinin-based combination therapies (ACTs) for a total of 3 days (see Table 133-3). If not possible to treat with one of the three recommended ACT regimens, oral artesunate can be combined with either clindamycin or doxycycline, or oral quinine plus either clindamycin or doxycycline can be used for a total of 7 days' course for both drugs. Doxycycline is preferred to other tetracyclines because it can be given once daily and does not accumulate in renal failure. Doxycycline is contraindicated, and thus clindamycin is preferred, in children and pregnant women (see Table 139-3). The dosage of artemisinin compounds does not need to be adjusted for patients with AKI or hepatic dysfunction.

Despite its use in most part of the world, artesunate is not licensed in many industrialized countries. In the United States, artesunate has the "investigational new drug" status and is available only through request to the Centers for Disease Control and Prevention (CDC) (770-488-7788).^{87,88} If no artemisinin drug is available, parenteral quinine or quinidine gluconate can be used as an alternative.^{85,86} Since IV quinine is also unavailable in the United States, quinidine gluconate is often used.⁸⁹ Cinchona alkaloids may also be considered in patients infected in Southeast Asia, where resistance to artemisinin compounds has been documented, and should be coadministered with artemisinin compounds.^{90,91} Chloroquine and sulfadoxine/pyrimethamine are no longer recommended for treatment of severe malaria.

Adverse Effects of Therapy

Side effects associated with artemisinin compounds are infrequent and generally mild and include abdominal pain, diarrhea, contact dermatitis, decreases in reticulocyte and neutrophil counts, and elevated hepatic transaminases.⁹² Severe allergic reactions and cerebellar dysfunction have been rarely reported.⁹³ In nonimmune adult travelers with high parasitemia, delayed hemolysis has been described after

administration of parenteral artesunate, and thus patients treated with this compound should be monitored for anemia for 1 month posttreatment.^{94,95}

Side effects of quinine and quinidine, known as *cinchonism*, are common and typically include nausea, vomiting, headache, dysphoria, vasodilation, tinnitus, and changes in auditory and visual acuity. These alterations are dose related and reversible. Less common side effects include rash, urticaria, angioedema of the face, pruritus, agranulocytosis, hepatitis, blackwater fever, and psychiatric disorders. Overdoses are associated with depressed respiration, circulatory collapse, and central nervous system (CNS) alterations including seizures and coma, which may be difficult to distinguish from cerebral malaria.⁹⁶ Simultaneous use of two quinolines or retreatment with the same quinoline within a short period may predispose to severe side effects.⁹⁷ The cinchona alkaloids are metabolized in the liver and excreted in the urine. Monitoring blood levels is recommended for persons with impaired renal or hepatic function, and dose reduction is necessary in those with severe renal impairment. Quinine metabolism appears to be decreased in children with kwashiorkor but increased in those with marasmus.⁹⁸

Although rarely clinically significant, prolongation of the electrocardiographic QT interval with IV quinoline therapy is common.⁹⁹ Severe conduction abnormalities may occur along with hypotension, blindness, and deafness.^{75,87-99} Dysrhythmias and hypotension may also result from overly rapid infusion. Coma may result when serum quinoline levels exceed 20 mg/L. Cardiac monitoring should be performed with IV quinoline use, especially with quinidine, which although more potent against the malarial parasite is also generally more toxic.⁹⁹ Infusion rates of quinidine should be decreased if the QT interval increases by more than 25% of its baseline level.

Quinoline-induced stimulation of insulin release may elicit significant hypoglycemia, especially in pregnancy.^{82,100} Hypophosphatemia may also be precipitated by both quinoline and IV dextrose, causing CNS dysfunction.⁵⁵ Levels of digoxin, mefloquine, neuromuscular blocking agents, and oral anticoagulants may all be increased with quinoline administration. Quinine can cause hemolysis in patients with G6PD deficiency. Because of their curare-like effect on skeletal muscle, quinolines are contraindicated in patients with myasthenia gravis. An extensive list of drug interactions reported for recommended antimalarial drugs is available in the WHO guidelines for treating malaria.⁷⁴

Ancillary Therapies

Various ancillary therapies have been proposed for severe malaria. In most cases, controlled data are not available to judge their efficacy. Exchange transfusion and erythrocytapheresis have been employed in cases of severe malaria with high parasitemia with apparent benefit.¹⁰¹⁻¹⁰⁴ However, a study encompassing 25 years of experience treating U.S. patients with severe malaria by exchange transfusion concluded that there was no survival benefit.¹⁰⁵ Treatments such as heparin, prostacyclin, desferrioxamine, pentoxifylline, low-molecular-mass dextran, urea, high-dose corticosteroids, aspirin, anti-TNF antibody, cyclosporine A, dichloroacetate, adrenaline, hyperimmune serum, *N*-acetylcysteine, and bolus administration of albumin are not recommended since their effectiveness is not proven or they have shown to be detrimental in severe malaria.^{41,74}

Laboratory Monitoring

Findings in severe malaria may include profound hemolytic anemia and thrombocytopenia, leukocytosis with a left shift (although milder cases may show leukopenia), prolonged coagulation times (with increased fibrin split products and diminished fibrinogen reflecting DIC), hyponatremia, hypoalbuminemia, hypophosphatemia, hypoglycemia, lactic acidemia, and elevated hepatic enzymes, LDH, bilirubin, blood urea nitrogen (BUN), and creatinine. Urinalysis may reveal proteinuria, RBCs and RBC casts, and hemoglobinuria. Coagulation

TABLE 133-4 Treatment Guidelines for Severe *Plasmodium falciparum* Malaria

| DRUG | DOSE | COMMENTS |
|-----------------------------------|--|--|
| ARTEMISININ COMPOUNDS | | |
| Artesunate | 2.4 mg/kg IV bolus at 0, 12, 24 hours, then daily until patient is able to transition to the following oral regimen: | Artesunate has “investigational new drug” status in the United States and is available only on request to the CDC (770-488-7788). Eligibility requirements include inability to take oral medications, high levels of parasitemia, clinical evidence of severe malaria, intolerance of or contraindication to quinidine, failure of quinidine therapy, and lack of rapid access to quinidine. ⁸⁸ Where available, artesunate rectal suppositories (10 mg/kg) may be used in children <5 years of age if IV or IM administration is not possible. Doxycycline is contraindicated in children <8 years of age and in pregnancy. Atovaquone/proguanil is packaged in the United States in fixed-dose combination tablets of 250 mg atovaquone/100 mg proguanil for adults and 62.5 mg atovaquone/25 mg proguanil for children. Safety of atovaquone/proguanil in pregnancy has not been established. |
| Artemether | 1. Artemether + lumefantrine: tablets containing 20 + 120 mg, 40 + 240 mg of artemether and lumefantrine, respectively <ul style="list-style-type: none"> Adults ≥35 kg: 80 + 480 mg twice daily for 3 days Children: <ul style="list-style-type: none"> 5 to <15 kg: 20 + 120 mg twice daily for 3 days 15 to <25 kg: 40 + 240 mg twice daily for 3 days 25 to <35 kg: 60 + 360 mg twice daily for 3 days | |
| | 2. Artesunate + amodiaquine: A fixed-dose combination tablet containing 25 + 67.5 mg, 50 + 135 mg, 100 + 270 mg of artesunate and amodiaquine, respectively <ul style="list-style-type: none"> Adults ≥36 kg, 200 + 540 mg daily for 3 days Children: <ul style="list-style-type: none"> 4.5 to <9 kg: 25 + 67.5 mg daily for 3 days 9 to <18 kg: 50 + 135 mg daily for 3 days 18 to <36 kg: 100 + 270 mg daily for 3 days | |
| | 3. Dihydroartemisinin (DHA) + piperazine (PPQ): Tablets containing 20 + 160 mg, 40 + 320 mg of DHA and PPQ, respectively <ul style="list-style-type: none"> Adults: <ul style="list-style-type: none"> 36 to <75 kg: 120 + 960 mg daily for 3 days ≥75 kg: 160 + 1280 mg daily for 3 days (no data on dose recommendation >100 kg) Children <ul style="list-style-type: none"> 5 to <7 kg: 10 + 80 mg daily for 3 days 7 to <13 kg: 20 + 160 mg daily for 3 days 13 to <24 kg: 40 + 320 mg daily for 3 days 24 to <36 kg: 80 + 640 mg daily for 3 days | |
| | 4. Artesunate or quinine PO to complete 7 days plus doxycycline, 100 mg PO BID × 7 days | |
| | 5. Artesunate or quinine PO to complete 7 days plus clindamycin, 20 mg base/kg/d PO, TID × 7 days | |
| | Initial dose: 3.2 mg/kg IM (anterior thigh); maintenance dose: 1.6 mg/kg IM daily until patient is able to transition to oral regimen as described earlier for artesunate | |
| CINCHONA ALKALOID REGIMENS | | |
| Quinine dihydrochloride | 20 mg salt/kg IV or IM on admission, then 10 mg/kg q 8 h. Can be given IM if IV administration is not possible. One of the following drugs should also be given concurrently: <ol style="list-style-type: none"> ACT as listed earlier. Doxycycline as listed earlier. If patient unable to take PO, give 100 mg IV q 12 h and switch to PO when possible. Avoid rapid IV administration. Clindamycin as listed earlier. If patient unable to take PO, give 10 mg base/kg loading dose IV followed by 5 mg base/kg IV q 8 h and switch to PO when possible. Avoid rapid IV administration. | The infusion rate of IV quinine should be rate controlled and not exceed 5 mg salt/kg per hour. The drug is usually diluted in 5% dextrose and infused over 4 hours. IV quinine is not available in the United States. When administering IM, the dose should be split and diluted to a concentration of 60-100 mg/kg and delivered to each thigh. Reduce the quinine dose by one-third (to 10 mg salt/kg q 12 h) after 48 hours in patients with severe renal and/or hepatic dysfunction. Doxycycline is contraindicated in children <8 years old and in pregnancy. |
| Quinidine gluconate | 6.25 mg base/kg (= 10 mg salt/kg) IV on admission over 1-2 hours, then 0.0125 mg base/kg minute (= 0.02 mg salt/kg per minute) continuous infusion. An alternative regimen is 15 mg base/kg (= 24 mg salt/kg) loading dose IV infused over 4 hours, followed by 7.5 mg base/kg (= 12 mg salt/kg) infused over 4 hours q 8 h, starting 8 hours after the loading dose. A second drug should be given concurrently as listed earlier for quinine. | The loading dose should be omitted if the patient received >40 mg/kg quinine in the preceding 48 hours or mefloquine in the previous 12 hours. Reduce the dose by one-third after 48 hours in patients with severe renal and/or hepatic dysfunction. |

BID, Twice a day; CDC, Centers for Disease Control and Prevention; DHA, dihydroartemisinin; IM, intramuscular; IV, intravenous; PO, by mouth; PPQ, piperazine; q8h, every 8 hours; TID, thrice a day.

defects and thrombocytopenia often correlate with the degree of parasitemia. The level of parasitemia should be monitored via blood smear every 12 hours after initiation of therapy. A decrease of 75% should be noted within 48 hours. If this does not occur, drug resistance should be suspected, and the regimen should be changed accordingly (see Table 133-4).

PROGNOSIS

Case fatality rates of severe malaria vary by geographic context and quality of care from 2% to 50%.^{31,32,115-117} More studies of treatment with artemisinin compounds in endemic areas generally report case fatality

rates of 10% to 19%.^{85,86} The case fatality associated with imported cases of *P. falciparum* malaria requiring ICU admission has been estimated to be between 4% and 29%.¹¹⁸ Factors that correlate with a poor prognosis include the infecting species and resistance profile, choice of parenteral therapy, CNS involvement, pulmonary edema, shock, hypoglycemia, lactic acidosis, renal failure, severe anemia, younger age, pregnancy, and treatment in a rural health facility as opposed to an ICU.^{55,119-126} There is a semiquantitative relationship between the level of parasitemia and risk of death, especially in nonimmune patients.

Although less than 10% of adults with cerebral malaria have persistent neurologic sequelae, this number may be as high as 40% in

children, especially if associated with hypoglycemia.^{81,115} Commonly seen sequelae include psychosis, hemiparesis, cerebellar ataxia, and extrapyramidal rigidity.^{31,32} Children who survive without obvious neurologic sequelae then appear to develop normally neuropsychologically.¹²⁷ A postmalaria neurologic syndrome, usually associated with mefloquine use, of an acute confusional state, psychosis, convulsions, and tremors has been described but is usually self-limited.³²

Acknowledgments

The authors thank Andrew Bennett, Jenna Iberg, Lara Schwarz Emily Jentes, Donald Krogstad, Nikki Maxwell, Corina Monagin, Laura Morgan, Obinna Nnedu, Christina Styron, Torrey Theall, and Kent Wagoner for their advice and assistance in preparing the manuscript.

KEY POINTS

1. A detailed history of patients' travel itinerary, activities and exposures, and any pretravel prophylaxis, as well as their general knowledge of the prevalent diseases and their incubation periods and drug resistance patterns in the region of travel are imperative when evaluating patients with exposures overseas.
2. Most "nontropical" infections are also common in developing countries and thus need to be considered.
3. Assessing patients' immune status based on their history of exposure to malaria is essential in directing the diagnostic workup and management.
4. Infection with multiple tropical pathogens is common in those living in endemic areas.

Risk of Infection and Uncomplicated Malaria

1. Malaria is the most common serious infection in most tropical countries, as well as in returning travelers, and therefore should be considered in any patient reporting travel to malaria-endemic areas or exposure to unscreened blood products ("transfusion malaria") or blood-contaminated needles.
2. Malaria classically produces a three-stage "paroxysm" progressing over an 8- to 12-hour period, consisting of rigors and chills ("cold stage"), followed by fever ("hot stage"), and subsequently sweating with resolution of all symptoms ("defervescent stage"). In practice, neither the classic paroxysm nor the periodicity is invariably seen.

Severe and Complicated Malaria

1. The overwhelming majority of severe and complicated malaria is due to *P. falciparum* in nonimmune children, adults, and pregnant women, but *P. vivax* and *P. knowlesi* can also cause severe disease.
2. The risk of acquiring *P. falciparum* is highest for those traveling to sub-Saharan Africa (especially West Africa) and New Guinea, moderate in India, and comparatively low in Southeast Asia and Latin America. *P. vivax* is widely distributed, with the highest risk in Oceania. *P. knowlesi* is restricted to Southeast Asia.
3. The most frequent severe complication is cerebral malaria, mostly seen in children and manifesting as coma, convulsions, changes in sensorium, or focal neurologic signs. Other severe complications include severe anemia (especially in young children and pregnant women), hypoglycemia, lactic acidosis, AKI, pulmonary edema, ARDS, shock, and bacterial suprainfection.
4. Potentially severe complications due to non-*falciparum* malaria include splenic rupture and severe anemia (*P. vivax*) and chronic nephrotic syndrome (*P. malariae*).

Diagnosis

1. Malaria often presents with nonspecific signs and symptoms, and the differential diagnosis is broad, so making a clinical diagnosis may be difficult.
2. The vast majority of malarial cases present within 1 month of exposure. *P. vivax* and *P. ovale* infections can present months, or even years, after infection because of the possibility of dormant forms (hypnozoites) in the liver.
3. Laboratory diagnosis is traditionally made through microscopy of thick and thin Giemsa-stained smears. Low or fluctuating parasitemias or altered parasite morphology may complicate diagnosis, especially with an inexperienced microscopist. Asymptomatic parasitemia is common in children from endemic areas.
4. Various new diagnostic techniques for malaria (e.g., dipstick antigen detection, PCR) have been developed, with sensitivities and specificities for *P. falciparum* generally similar or better than conventional microscopy. Use of one of these new modalities should be considered when the diagnosis of malaria is unclear.
5. Radiographic imaging of the abdomen is indicated when splenic rupture is suspected.

Clinical Management

1. Patients with evidence of severe or complicated malaria should be assumed to have chloroquine-resistant *P. falciparum* and admitted to the ICU for aggressive supportive care and urgent antimalarial drug therapy. Therapy should consist of IV artesunate followed by oral ACT for 3 days. Parenteral artesunate should be given for at least 24 hours and until the patient is able to tolerate oral medication. Acceptable alternatives to parenteral artesunate/ACT include IM artemether, IV quinidine gluconate, or IV quinine (transitioned to oral artesunate or quinine according to the same aforementioned criteria) given simultaneously with oral/IV doxycycline or clindamycin for 7 days.
2. Artemisinin compounds are usually well tolerated. Side effects with cinchona alkaloid therapy are frequent but are usually mild, dose related, and reversible.
3. Many patients with splenic rupture can be managed conservatively with supportive therapy, although splenectomy may be necessary.
4. The hemoglobin/hematocrit, electrolytes, platelet count, glucose, lactate, arterial blood gas, BUN/creatinine, liver function and coagulation enzymes, and level of parasitemia in response to therapy should be monitored closely.
5. The case fatality rate of severe malaria treated in an ICU is estimated to be 9%.

ANNOTATED REFERENCES

Cox-Singh J, Davis TM, Lee KS, et al. *Plasmodium knowlesi* malaria in humans is widely distributed and potentially life threatening. Clin Infect Dis 2008;46:165–171.

P. knowlesi has been misdiagnosed as *P. malariae* in humans. In this study, 960 blood samples from hospitalized malaria patients and 54 archival blood samples previously diagnosed as *P. malariae* in Malaysian Borneo, in addition to 5 archival samples from peninsular Malaysia, were subjected to nested PCR. *P. knowlesi* was detected in 27.7% of samples from hospitalized patients, 83.7% of archival samples in Borneo, and 100% of samples from peninsular Malaysia. Since *P. knowlesi* is frequently misdiagnosed and has been implicated in severe disease, all patients with *P. malariae* contracted in Southeast Asia should be treated for severe *falciparum* malaria.

Mohan A, Sharma SK, Bollineni S. Acute lung injury and acute respiratory distress syndrome in malaria. J Vector Borne Dis 2008;45:179–193.

*The acute respiratory distress syndrome is a dangerous complication of severe *falciparum* malaria. Mechanisms of pathogenesis are proposed but not well understood. This review article details the difficult management of fluid balance and mechanical ventilation in the setting of respiratory compromise in severe malaria.*

Stauffer WM, Cartwright CP, Olson DA, et al. Diagnostic performance of rapid diagnostic tests versus blood smears for malaria in US clinical practice. Clin Infect Dis 2009;49:908–913.

*The diagnosis of malaria is difficult in countries where few cases are seen, and clinicians and laboratorians are thus unfamiliar with the disease. This prospective study of 852 blood samples compared testing by standard thick and thin smears with a rapid antigen capture assay. The sensitivity of rapid diagnostic test was 97% and 100% for all malaria and *P. falciparum*, respectively, compared to 85% and 88% by Giemsa-stained thick blood smear. Rapid diagnostic tests are recommended, especially, for inexperienced microbiologists.*

Acute infections with viruses produce a variety of clinical manifestations with a wide spectrum of clinical severities. Viral upper respiratory tract infections in immunocompetent hosts are usually trivial, although they may be life-threatening and associated with subsequent lower respiratory tract infection and disseminated disease in immunocompromised hosts. Respiratory virus infections, including those responsible for MERS and SARS, are described elsewhere in this book.

Viral infections can affect virtually every organ system and have a variety of clinical manifestations. These are described below.

VESICULAR RASH

Poxviruses Including Smallpox and Monkeypox

Poxviruses are double-stranded DNA viruses that are relevant because of concerns regarding possible bioterrorism with smallpox.^{1,2} Additionally, outbreaks of monkeypox infection in humans have been detected, albeit rarely.³ The poxviruses and their major clinical manifestations are listed in Table 134-1. In general, a common feature of poxviruses is that they cause vesicular skin eruptions.

Smallpox

The last case of endemic smallpox occurred in Somalia in 1977, and it was declared in 1980 that the disease was eradicated.⁴ The virus (variola) has been maintained in some laboratories—the last known case of laboratory-acquired smallpox occurred in the United Kingdom in 1978. In part, as a result of this accident, the number of laboratories that retained the virus was reduced from 76 to 2. These laboratories are at the Centers for Disease Control and Prevention (CDC) in Atlanta in the United States and the Vektor Institute in Novosibirsk in Russia. It is not known if all the other laboratories destroyed their stocks of viruses—therefore, the potential exists for a deliberate release of variola as an act of bioterrorism.^{1,5}

The incubation period for smallpox is 7 to 17 days (mean, 10-12 days).⁴ A prodromal phase consisting of the abrupt onset of severe headaches, backaches, and fever occurs. The fever often reaches 40°C and then subsides. This is followed by a rash; initial lesions are small, red macules, which become vesicles over the next 2 to 3 days. The lesions first appear on the face and extremities and then cover the entire body including the palms and soles of feet. Subsequently, these lesions may umbilicate and crust.

The rash of smallpox could be confused with monkeypox, generalized vaccinia and eczema vaccinatum, chickenpox, coxsackievirus infection, herpes simplex virus (HSV) infection (especially eczema herpeticum), rickettsialpox, insect bites, drug eruptions, and acne. A classic feature of smallpox is that the lesions are all at the same stage of development. In contrast, chickenpox has individual lesions present at different stages of development. With chickenpox, fever occurs with the onset of the rash.

It is well known that smallpox is associated with significant mortality; however, it is not clear what the likelihood of mortality would be in patients who receive good supportive care, such as that which exists in modern intensive care units (ICUs). There are many reasons for the mortality associated with smallpox. Substantial amounts of fluid and protein are lost by febrile patients with numerous weeping lesions. In

some patients, death may occur before the appearance of any rash since this prodromal period is associated with significant viremia. A hemorrhagic form of smallpox is also associated with high mortality.⁴ Encephalitis occurs in less than 1% of infected patients. Secondary bacterial infections of the skin lesions may occur and are heralded by a second temperature spike.⁴ Although cough is not usually a prominent symptom of smallpox, secondary bacterial pneumonia may occur, particularly in patients with severe disease.

The CDC recommends an algorithmic approach for the diagnosis of smallpox. Patients are subdivided into low-risk, moderate-risk, and high-risk groups depending on a variety of variables (Boxes 134-1 and 134-2). Patients at low or moderate risk of smallpox should undergo polymerase chain reaction (PCR) testing of the skin lesion for varicella-zoster virus (VZV) infection, HSV, and enterovirus. Patients at moderate risk undergo consultation by infectious disease or dermatology specialists. Electron microscopy should be performed if PCR for these viruses is negative. If rapid testing for VZV and HSV is negative for moderate-risk patients, the adequacy of specimen collection should be confirmed. If there is ongoing clinical suspicion of smallpox, local and state health departments should be consulted. For patients at high risk of smallpox, all testing should be performed at the CDC. This testing should include variola real-time PCR, *Orthopoxvirus* real-time PCR, and nonvariola *Orthopoxvirus* real-time PCR, in addition to tests for VZV, HSV, and enteroviruses.

There is no approved treatment for smallpox.⁴ Prevention of secondary cases is crucial. A suspected case of smallpox should be managed in a negative-pressure room. Additionally, strict respiratory and contact isolation is essential (detailed instructions are available at <http://www.bt.cdc.gov/agent/smallpox>).⁴

Vaccinia

Vaccinia is the poxvirus used in smallpox immunizations. The primary vaccination results in a vesicle at the site of vaccination, usually within 3 to 5 days. This vesicle becomes pustular or is surrounded by induration or congestion 6 to 8 days after vaccination. In rare cases, a generalized rash characterized by multiple small, vesicular lesions occurs. Occasionally, severe complications result from smallpox vaccinations. If vaccinia is administered to patients with an immunologic deficiency, progressive necrosis at the site of vaccination may occur (vaccinia necrosum). Second, lesions may spread to other parts of the body. Such cases may be fatal. Patients with eczema may develop dissemination of vaccinia virus in the abnormal skin, leading to a generalized rash (eczema vaccinatum or Kaposi varicelliform eruption). Vaccinia immunoglobulin (0.6 mL/kg every 24 hours) can be prescribed for disseminated infection.

Encephalitis due to vaccinia may occur 1 to 2 weeks after vaccination and is associated with a mortality of 10% to 30%. Myocardial infarction, pericarditis, myocarditis, and dilated cardiomyopathy have been observed after smallpox vaccinations. In 2003, 37,901 potential bioterrorism first responders received the smallpox vaccine in the United States. There were 822 reports of adverse events; 100 of the 822 were serious, resulting in 85 hospitalizations, 2 permanent disabilities, 10 life-threatening illnesses, and 3 deaths. Among the 100 serious adverse events, 21 cases were myocarditis and/or pericarditis, 10 cases were ischemic cardiac events, 2 cases were generalized vaccinia, and 1 case was postvaccinial encephalitis. Serious adverse events were

TABLE 134-1 Common Clinical Manifestations of Poxviruses

| VIRUS | CLINICAL MANIFESTATIONS |
|--------------------|---|
| Variola (smallpox) | Diffuse vesicular rash; systemic disease |
| Monkeypox | Vesicular rash |
| Vaccinia (cowpox) | Vesicular rash; postinfectious encephalitis |
| Parapoxvirus | Orf (localized vesicular lesion) |
| Molluscipoxvirus | Molluscum contagiosum |
| Tanapox virus | Vesicular rash |

BOX 134-1 Criteria for the Suspicion of Smallpox in Patients with Acute Generalized Vesicular or Pustular Rash**MAJOR SMALLPOX CRITERIA**

Febrile prodrome

>101°F, 1-4 days before rash onset, with headache, backache, or abdominal pain

Firm, deep-seated, well-circumscribed vesicles/pustules

Lesions in the same stage of development in any one area of the body

MINOR SMALLPOX CRITERIA

Centrifugal distribution

First lesions in the pharynx, oral mucosa

Patient appears "toxic"

Slow evolution of the rash

1-2 days each stage: macule, papule, vesicle

Lesions on palms and soles

BOX 134-2 Categorization of Risk of Smallpox from Clinical Criteria***HIGH RISK OF SMALLPOX**Febrile prodrome *and*Classic smallpox lesion *and*

Lesions in the same stage of development

MODERATE RISK OF SMALLPOXFebrile prodrome *and* one other *major* smallpox criterion *or*Febrile prodrome *and* four *or* more minor smallpox criteria**LOW RISK OF SMALLPOX**No febrile prodrome *or*Febrile prodrome *and* fewer than four minor smallpox criteria

*The major and minor criteria are listed in Box 134-1.

more common among older revaccinees than in younger first-time recipients.⁶

From December 2002 to January 2004, the U.S. Department of Defense vaccinated 578,286 military personnel with vaccinia.⁶ Thirty cases of suspected contact transfer of vaccinia were reported.⁶ *Contact transfer* is the spread of vaccinia from a recipient of the smallpox vaccine to another person. This spread occurs because the live virus used in the vaccine is present on the skin at the site of the vaccination. Spread of the virus to other parts of the body (autoinoculation) also can occur via the same mechanism. No cases of vaccinia necrosum or eczema vaccinatum were observed in the people with contact transfer of the virus.

Monkeypox

Monkeypox was first recognized in 1958 as a disease of primates. Subsequently, the disease was recognized in rodents. Beginning in

1970, cases in humans were reported in Central Africa.⁷ In 2003, cases occurred in the United States in residents of the Midwest who had contact with imported prairie dogs.³ Patients developed vesicular skin lesions and fever/sweats. Although case fatality rates of 4% to 22% have been observed in outbreaks of the infection in Africa, none of the 11 patients in the American outbreak died.³

Herpesviruses

HSV, VZV, and herpes B virus are all capable of causing vesicular skin rash and other systemic manifestations of disease. The herpesviruses are large, enveloped DNA viruses that exhibit lifelong latent infection.^{8,9} The eight known human herpesviruses are HSV types 1 and 2; VZV; cytomegalovirus (CMV); human herpesvirus (HHV) types 6, 7, and 8; and Epstein-Barr virus (EBV).

Herpes Simplex Virus

HSV infections are found worldwide. Characteristically, HSV-1 is associated with orolabial disease, and HSV-2 is associated with genital infection, although this is not a rigid distinction. Primary infections (first infections with HSV-1 or HSV-2) are usually associated with mucosal lesions and systemic signs and symptoms. Mucosal and cutaneous lesions are vesicular and usually localized, although disseminated infection may occur rarely. Patients with atopic eczema or severe burns may develop extensive infections.

Primary HSV infections may have severe complications. Aseptic meningitis may occur and is more common with HSV-2. Meningeal symptoms usually start 3 to 12 days after the onset of genital lesions. Transverse myelitis and autonomic nervous system dysfunction may also occur in conjunction with primary genital HSV infection. HSV encephalitis in adults usually is not associated with primary infection. Potentially, reactivation of latent HSV-1 infection in trigeminal or autonomic nerve roots may be associated with the extension of virus into the central nervous system (CNS) via the enervation of the middle cranial fossa. Occasionally, patients with primary HSV infection develop hepatitis, pneumonia, or thrombocytopenia. These complications may be life-threatening and require ICU admission.

By virtue of the establishment of latency, HSV-1 or HSV-2 may reactivate. HSV reactivations may be less severe than primary infections. In immunocompromised hosts, however, reactivation of HSV-1 or HSV-2 may be associated with disseminated infection or severe local esophagitis, hepatitis, or pneumonia. Neonatal herpes, occurring in infants of mothers with primary or reactivated infection at the time of delivery, carries a high risk of disseminated fatal infection.

HSV-1 encephalitis is frequently seen in the ICU and is characterized by confusion or coma, accompanied by cerebrospinal fluid (CSF) lymphocytosis. Magnetic resonance imaging (MRI) of the brain may show temporal lobe lesions. Testing of CSF by PCR for HSV-1 is typically positive.

Diagnosis of HSV-1 or HSV-2 infections causing vesicular skin lesions can be suspected clinically by the presence of multiple vesicular lesions on an erythematous base, occurring in the orolabial or anogenital areas. A precise diagnosis can be established easily by PCR on scrapings from the lesions. Results can be available within hours of specimen collection.

Varicella-Zoster Virus

Primary VZV infections cause chickenpox, whereas reactivated infections cause shingles (zoster). Chickenpox is characterized by multiple vesicular lesions, whereas shingles is characterized by a unilateral vesicular eruption with a dermatomal distribution. Immunocompromised patients with shingles may develop disseminated cutaneous infection that may resemble chickenpox.

Chickenpox is usually associated with fever, constitutional symptoms, and a vesicular skin rash. Most skin lesions are small vesicular lesions with an erythematous base. Successive crops of lesions occur over 2 to 4 days, so lesions at all stages from fresh vesicles to crusted lesions are present simultaneously.

Secondary bacterial infections of vesicular lesions are relatively common, with infections involving *Staphylococcus aureus* and *Streptococcus pyogenes* being the most common. One manifestation of secondary bacterial infection is the occurrence of fever after the fever associated with the onset of chickenpox has subsided. Severe infection often results in toxic shock syndrome.^{10,11}

Chickenpox is associated with pneumonia in 1 in 400 cases of infection.^{12,13} A larger proportion of people may have some pulmonary involvement, but it is typically asymptomatic. Pregnant women and immunocompromised patients are at high risk of life-threatening pneumonia. Chickenpox pneumonia is generally manifested by cough and shortness of breath 3 to 5 days after the onset of the rash. Chest radiography typically shows a reticulonodular infiltrate. Respiratory failure may occur.

Neurologic complications of chickenpox include encephalitis, acute cerebellar ataxia (1 in about 4000 cases),¹⁴ and cerebral angiitis. Encephalitis due to VZV is less common than pneumonia but nevertheless may be life-threatening. The typical manifestation is onset of headaches followed by depression occurring in adults within 2 weeks of the chickenpox. Acute cerebellar ataxia is more common in children 1 to 3 weeks after the onset of chickenpox. Ataxia and slurred speech may occur but usually with complete resolution.

As with HSV infections, the rash of chickenpox or shingles can usually be diagnosed confidently on clinical grounds or confirmed by PCR of scrapings of skin lesions. PCR can also be performed on CSF to diagnose VZV encephalitis.¹⁴

Herpes B Virus (*Cercopithecine Herpesvirus 1*)

Herpes B virus (cercopithecine herpesvirus 1) infection is a relatively benign disease in monkeys. However, herpes B virus infection in humans, usually occurring from monkey bites or scratches, is a severe and potentially fatal disease. Monkeys of the *Macaca* genus (rhesus and cynomolgus monkeys) are considered to be at the highest risk. An incubation period of 2 to 14 days is usually observed after the bite or scratch. Initial symptoms are nonspecific but include fever, malaise, and headache. A cluster of small vesicles may occur at the bite site. Severe encephalomyelitis may ensue, with death occurring in days. In the United States, only one reference laboratory is equipped to identify the virus. Prompt and exhaustive cleaning of wounds, followed by early initiation of acyclovir or valacyclovir, may prevent the occurrence of severe disease. Additional information with contacts is available at <http://www.cdc.gov/niosh/docs/99-100/>.^{15,16}

FEVER IN IMMUNOCOMPROMISED PATIENTS

Numerous viruses can cause fever as a presenting symptom. In the absence of specific manifestations such as pneumonia or encephalitis, viral infections are rarely life-threatening. The onset of fever in immunocompromised individuals may, however, be the harbinger of severe overwhelming viral infection.

Cytomegalovirus

CMV infection is a classic cause of severe infection in immunocompromised hosts, especially transplant recipients and patients with human immunodeficiency virus (HIV) infection.¹⁷⁻¹⁹ Infection can be primary or due to reactivation. The risk of end organ CMV infection depends on the degree of immunosuppression and whether the infection is primary or reactivated. For solid organ transplant recipients, there is a significant risk of primary infection in patients who were seronegative for CMV before transplantation and received an organ from a seropositive donor.^{17,19}

The organs commonly affected by CMV infection include the esophagus, colon, retina, and lungs. Virtually any organ can be infected, including the CNS. Some patients present with fever, malaise, and hematologic abnormalities, without specific end organ abnormalities.

Given the high risk of CMV infections in solid organ transplant recipients, strategies should be employed to prevent CMV infections.^{17,20,21} Two options are prophylaxis or preemptive therapy. *Prophylaxis* implies the administration of preventive therapy to all persons at risk.¹⁷ In contrast, *preemptive* therapy is the administration of antiviral therapy only to persons at highest risk, as determined by a positive result on a regularly monitored blood test for CMV infection.¹⁷ Such therapy is given even if the patient is asymptomatic. Detection of CMV by PCR is used most often for early detection of CMV infection.

Epstein-Barr Virus

Primary EBV infection may be associated with fever, malaise, and hematologic abnormalities in immunocompromised patients (and also in some immunocompetent individuals). EBV infection may be associated with the development of malignancies such as posttransplant lymphoproliferative disorder.²²⁻²⁴ In some transplant populations, regular quantitative monitoring of EBV in peripheral blood by PCR is performed to determine the risk of significant EBV infection.²⁵

Human Herpesvirus 6

HHV-6 is a ubiquitous viral infection that usually occurs in infancy. Primary HHV-6 infection and possibly reactivation of infection in immunocompromised patients can be associated with serious disease.^{26,27} HHV-6 seems to have neurotropism—in addition to fever, HHV-6 infection may be associated with confusion, coma, and seizures.^{28,29} Occasionally, CSF examination is normal except for increased protein and the finding of HHV-6 by PCR.

Human Herpesvirus 8

HHV-8 is associated with Kaposi sarcoma, primary effusion lymphoma, and Castleman syndrome.^{30,31} It may be transmitted via organ allograft in solid organ transplantation. Primary infection in immunosuppressed patients may be associated with high fever, thrombocytopenia and other severe cytopenias, and mental state abnormalities.³² Detection of HHV-8 by PCR in whole blood can establish the diagnosis.

West Nile Virus and Zika Virus

In the 1990s, West Nile virus infection was detected in North America for the first time.^{33,34} Although many cases of infection were directly from the vector of infection (mosquitoes), other cases were via blood transfusion or organ allograft.^{35,36} West Nile virus exhibits neurotropism; infected patients may experience confusion and headaches in addition to fever and other more general symptoms.

Although Zika virus was described some decades ago, it has come to significant attention in 2015 and 2016. Most infected patients have minor symptoms with rash and fever. However, some adult patients may have more significant infection. In utero transmission may result in microcephaly and significant developmental problems in the child.

Adenovirus

Adenoviruses have a myriad of presentations in immunocompetent and immunocompromised hosts. Adenovirus infection in immunocompetent individuals is rarely associated with severe disease.³⁷ Although adenovirus infection in immunocompromised hosts may have trivial manifestations, severe diseases may certainly occur. In recipients of hematologic stem cell transplantation, adenoviruses may cause interstitial pneumonitis, hepatitis including ascending cholangiohepatitis, hemorrhagic cystitis, nephritis, hemorrhagic colitis, CNS disease, and disseminated disease.³⁷ In solid organ transplant recipients, the primary site of adenovirus disease is usually related to the transplanted organ. Clinical manifestations of adenovirus infections described in solid organ transplantations include pneumonia, hepatitis, nephritis, hemorrhagic cystitis, enteritis, and disseminated disease.³⁷

Adenovirus infection in patients with HIV may cause pneumonia, hepatitis, meningoencephalitis, nephritis, and gastrointestinal and disseminated disease.³⁷

Polyomaviruses

The most commonly encountered polyomaviruses are JC virus and BK virus. JC virus may be associated with progressive multifocal leukoencephalopathy, a progressive and ultimately fatal neurologic disease occurring in profoundly immunosuppressed individuals, such as patients with advanced HIV infection. BK virus is associated most commonly with renal infection in renal transplant recipients.³⁸ This infection is usually not accompanied by systemic manifestations such as fever. Infected patients have steadily rising serum creatinine. This presentation may be mistaken for acute rejection. Treatment with augmented immunosuppression is contraindicated, however, in patients with BK virus–associated nephropathy. Instead, immunosuppression should be minimized.

■ VIRAL HEMORRHAGIC FEVERS

Hemorrhagic fevers may be due to Filoviridae, Bunyaviridae, Arenaviridae, or Flaviviridae. Dengue hemorrhagic fever is not discussed in this chapter because it is reviewed in detail elsewhere in this book.

Marburg and Ebola Virus Hemorrhagic Fevers

Marburg virus and Ebola virus are members of the *Filovirus* genus. Marburg virus appears to have originated in Uganda and Western Kenya, where it infected monkeys and subsequently humans. *Marburg* refers to a town in Germany where monkeys from Uganda infected medical researchers, who subsequently infected hospital staff. The major subtypes of Ebola virus have occurred in Central Africa. An additional subtype (Reston) was discovered in Reston, Virginia, among infected monkeys imported from the Philippines.³⁹ The source of this infection has not been definitively determined.

Marburg and Ebola virus infections have an incubation period of 5 to 10 days and begin with the abrupt onset of fever, myalgia, and headache. Somnolence and delirium usually follow. Most patients have abdominal pain and diarrhea. Many have a maculopapular rash on the trunk. Hemorrhagic manifestations such as bleeding around needle puncture sites and from the mucous membranes become prominent. Most patients have significant thrombocytopenia, leukopenia, and elevated transaminase levels. Viral culture, serology, and PCR have all been used to establish the diagnosis. At present, management is purely supportive. Additionally, strict contact isolation precautions are necessary.

Hanta Fever and Crimean-Congo Hemorrhagic Fever

Hantavirus and Crimean-Congo hemorrhagic fever (CCHF) virus (CCHFV) are from the Bunyaviridae family of viruses. Hantaviruses cause hemorrhagic fever with renal syndrome (HFRS) and hantavirus pulmonary syndrome (HPS). There are several human pathogenic strains of hantavirus. The subtypes Hantaan, Dobrava, and Seoul cause moderate to severe HFRS in Asia and Europe, whereas Puumala causes a mild form of HFRS.⁴⁰ Unlike other Bunyaviridae, hantaviruses do not appear to have an arthropod vector and are usually transmitted via aerosols of virus-contaminated rodent urine or feces. The incubation period is typically 2 weeks. Initially, patients develop fever, headache, dizziness, blurred vision, abdominal pain, and back pain. Petechiae may be evident on the palate and the trunk; most patients have significant thrombocytopenia. After 4 to 7 days, significant hypotension can occur. In patients who survive, oliguria and mucosal hemorrhage occur, followed by polyuria. Sin Nombre virus and Andes virus cause HPS in North America and South America, respectively.⁴⁰

CCHF is a severe hemorrhagic fever with a mortality rate ranging from 3% to 30%; it has been described in parts of Africa, Asia, Eastern Europe, and the Middle East.⁴¹ It has the most extensive geographic distribution of medically important tickborne viral diseases. CCHF occurs through tick (*Hyalomma* spp.) bites, by contact with blood or tissues from viremic livestock, and after contact with patients with CCHF during the acute phase of infection.⁴¹ Patients have severe thrombocytopenia, disseminated intravascular coagulation, and extensive bleeding, with increased levels of liver enzymes, creatinine phosphokinase, and lactate dehydrogenase. Diagnosis is made by enzyme-linked immunoassay (ELISA) and PCR. The clinical course of CCHF is composed of an incubation period (3–7 days), a prehemorrhagic period (3–7 days) characterized by flu-like symptoms, a hemorrhagic period (2–3 days), and a convalescence period. Supportive therapy is the most essential part of the management of CCHF. Ribavirin (30 mg/kg as an initial dose, then 15 mg/kg 6-hourly for 4 days, then 7.5 mg/kg 8-hourly for 6 days) is the recommended antiviral agent for severe CCHF, although its mechanism of action is unknown.⁴¹

Lassa Fever and South American Hemorrhagic Fevers

Lassa fever and South American hemorrhagic fevers are due to the Arenaviridae. Lassa fever occurs in West Africa. South American hemorrhagic fevers occur in Argentina, Bolivia, and Venezuela. Lassa fever is transmitted via rodents, but subsequent nosocomial transmission has been extensive. Many cases of Lassa fever are only mildly symptomatic. Some patients develop high fever, pharyngitis, and retrosternal chest pain accompanied by significant mucosal bleeding. Hypotension, renal failure, and pulmonary edema may follow. Serology can be used to establish the diagnosis, but the virus is also easily isolated from blood during the first week of illness, when viremia is often striking.⁴² Use of ribavirin has been associated with a decrease in mortality.⁴²

South American hemorrhagic fevers (Argentine, Bolivian, and Venezuelan) usually present with unremitting fever accompanied by a variety of nonspecific symptoms. Petechiae are often present on the palate and the skin, especially the axilla; mucosal bleeding may result. Pulmonary edema may occur. Management is extremely difficult owing to the combination of hypotension and refractory pulmonary edema. The diagnosis can be established by serologic tests. No specific therapy is available.

2009 PANDEMIC INFLUENZA A AND AVIAN INFLUENZA A

The rapid dramatic increase in the frequency of severe illness due to the 2009 influenza A(H1N1) has affected intensive care facilities around the world.^{43–45} Suggested risk factors for severe illness associated with the 2009 H1N1 infection include age (<5 years or ≥65 years), pregnancy, chronic cardiovascular conditions, chronic lung disorders, diabetes, immunosuppression, morbid obesity, hemoglobinopathy, chronic renal disease, chronic hepatic disease, and a long history of smoking.⁴⁶ Therapy with neuraminidase inhibitors (e.g., oseltamivir, zanamivir) is especially important for patients with such risk factors, as well as pregnant women. Epidemiologic studies estimated the case fatality ratio to be 0.05% to 0.5%.⁴⁷ However, as more than three-quarters of cases of the 2009 influenza A(H1N1) pandemic occurred in persons younger than 30 (with a peak in the group aged 10 to 19 years), years of life lost are estimated to be 3 to 5 times higher than for typical seasonal influenza and of the same order as the 1968 pandemic.⁴⁷

Avian influenza A(H5N1) virus remains a cause for concern. The first human case of influenza A(H5N1) virus infection was documented in Hong Kong in 1997.⁴⁸ Since its reemergence in 2003, it has caused human cases in 15 countries (e.g., China, Egypt, Indonesia, Iraq, Nigeria, Thailand, Turkey, Vietnam) around the world.^{49–53} The cumulative number of cases of avian influenza A(H5N1) virus infections

reported to the WHO as of June 8, 2010, was 499, with 295 subsequent deaths representing a mortality rate of approximately 60% (http://www.who.int/csr/disease/avian_influenza/country/en/). Although it has limited ability for human-to-human transmission, the continued circulation of influenza A(H5N1) virus increases the possibility of the reassortment of this virus with other circulating human influenza A viruses and increases the threat of a global influenza pandemic.⁵⁰

HENDRA AND NIPAH VIRUSES

These paramyxoviruses have been associated with deaths due to encephalitis or an acute pulmonary syndrome in Australia (Hendra virus) and Malaysia, Singapore, India, and Bangladesh (Nipah virus). The reservoir for these closely related viruses appears to be fruit bats. Viral transmission appears to occur from bats to horses (Hendra virus) or pigs (Nipah virus). Humans exposed to ill horses or pigs have developed the fatal infection. In Bangladesh, nosocomial transmission of Nipah virus may have occurred.

OTHER ACUTE VIRAL SYNDROMES

Many viruses can cause aseptic meningitis, encephalitis, pneumonia, or hepatitis. These viruses are summarized in [Tables 134-2, 134-3, and 134-4](#).

ANTIVIRAL DRUGS

Since the advent of HIV infection, there has been an increase in the development of drugs active against viruses. This section describes the currently available antiviral drugs, with the exception of drugs for HIV and viral hepatitis.

Acyclovir

Acyclovir is a deoxyguanosine analog that inhibits viral DNA polymerase. When incorporated into viral DNA, it acts as a chain terminator. Acyclovir has its greatest clinical utility against HSV-1, HSV-2, and

VZV. It has some activity against CMV, but it is far inferior to ganciclovir for infections with this virus. Acyclovir-resistant HSV has been well described, whereas acyclovir-resistant VZV is rare. Acyclovir is available in oral and intravenous (IV) forms. It penetrates the CSF reasonably well, and CSF levels are about 50% of plasma levels.⁴³ Dosing for acute mucosal HSV infections is 200 mg, five times a day, administered orally, and for VZV infections is 800 mg, five times a day, administered orally. In HSV encephalitis, the usual dose is 10 mg/kg given IV every 8 hours. Dose reduction is required in the presence of renal dysfunction. In the absence of appropriate reduction in dosage for renal dysfunction, neurotoxicity is observed, usually manifesting as confusion, hallucinations, and occurrence of tremors. As acyclovir can cause crystalline nephropathy, patients receiving the drug should be well hydrated.

Valacyclovir

Because the bioavailability of orally administered acyclovir is low, valacyclovir (the L-valyl ester prodrug of acyclovir) was developed. It is usually administered twice daily for HSV infections and three times daily for VZV infections. Valacyclovir is also used for the prevention of CMV disease in renal transplant recipients.⁵⁴

Famciclovir

Famciclovir lacks antiviral activity but is the prodrug of penciclovir, which is active against HSV and VZV. Similar to acyclovir, penciclovir is an inhibitor of viral DNA synthesis. In general, acyclovir-resistant strains are also resistant to penciclovir. Dose adjustment of famciclovir is needed in renal insufficiency.

TABLE 134-2 Viruses That Cause Aseptic Meningitis or Encephalitis

| VIRUS | IMPORTANT CLINICAL FEATURES |
|------------------------------|---|
| Enteroviruses | Common cause of aseptic meningitis; rapid diagnosis available via PCR of CSF |
| HSV | In adults usually due to reactivation; rapid diagnosis available via PCR of CSF |
| VZV | Uncommonly may cause encephalitis after chickenpox |
| HHV-6 | Causes encephalitis in transplant recipients |
| JK virus | Causes progressive multifocal leukoencephalopathy |
| Japanese encephalitis | Endemic in parts of Asia |
| St. Louis encephalitis | Outbreaks have occurred in all U.S. states |
| West Nile virus | Now common in U.S. and Canada |
| Tickborne encephalitis | Several foci of infection |
| Nipah virus | Zoonosis occurring in Malaysia, Singapore, India, and Bangladesh |
| Hendra virus | Zoonosis occurring in Australia |
| Rabies virus | Well-known zoonosis |
| California encephalitis | La Crosse virus is responsible for most cases |
| Human immunodeficiency virus | May cause acute encephalitis |

CSF, cerebrospinal fluid; HSV, herpes simplex virus; HHV-6, human herpesvirus 6; PCR, polymerase chain reaction; VZV, varicella-zoster virus.

TABLE 134-3 Viruses That Cause Pneumonia

| VIRUS | IMPORTANT CLINICAL FEATURES |
|-----------------------------|--|
| Respiratory syncytial virus | Common cause of infection in infants |
| Influenza | Well-known cause of respiratory infection |
| Parainfluenza virus | Croup and pneumonia |
| Measles virus | Leading cause of pneumonia in children in underdeveloped nations |
| Coronaviruses | Severe acute respiratory syndrome |
| CMV | Important cause of pneumonia in immunosuppressed hosts |
| VZV | Pneumonia can complicate chickenpox |
| Adenovirus | Ubiquitous virus; severe pneumonia in immunosuppressed hosts |
| Hantavirus | Severe pneumonia in immunocompetent hosts |
| Hendra virus | Zoonosis in Australia |

CMV, cytomegalovirus; VZV, varicella-zoster virus.

TABLE 134-4 Viruses That Cause Hepatitis

| VIRUS | IMPORTANT CLINICAL FEATURES |
|-------------------|---|
| Hepatitis A virus | Fecal-oral transmission |
| Hepatitis B virus | Parenteral, sexual, vertical transmission |
| Hepatitis C virus | Parenteral transmission |
| Hepatitis D virus | Requires coinfection with hepatitis B |
| Hepatitis E virus | Fecal-oral transmission |

Ganciclovir

Similar to acyclovir, ganciclovir is a deoxyguanosine analog. It has activity against HSV and VZV. Its primary use has been in the treatment or prevention of CMV infections. Ganciclovir acts by inhibiting viral DNA polymerases. Patients with end organ disease due to CMV are treated initially with ganciclovir, 5 mg/kg IV every 12 hours. Alterations in dose and frequency are required in patients with renal dysfunction. Typically, maintenance therapy is given at a reduced frequency (e.g., once per day) in patients who have received 2 to 3 weeks of induction therapy. Myelosuppression is the major toxicity of ganciclovir. Neutropenia typically begins to occur in the second week of ganciclovir therapy. Regular monitoring of hematologic parameters is mandatory for patients receiving ganciclovir. CNS abnormalities such as headaches and confusion have been well described in patients receiving ganciclovir. In addition to an IV preparation, ganciclovir is available in an orally administered form. This form may be useful as a prophylaxis against CMV infections.¹⁷ Ganciclovir also can be administered into the eyes via an ocular implant.^{55,56} Ganciclovir is less active against acyclovir-resistant HSV strains than against acyclovir-susceptible strains. Resistance of CMV to ganciclovir has been well described, and mutations in the *UL97* phosphotransferase gene are generally associated with ganciclovir resistance.^{17,57} Risk factors for ganciclovir resistance include prolonged exposure to ganciclovir (usually several months), ongoing active viral replication due to severe immunosuppression, lack of prior CMV immunity, and inadequate antiviral drug delivery with oral ganciclovir.¹⁷

Valganciclovir

The oral bioavailability of ganciclovir is poor. Valganciclovir, a prodrug of ganciclovir, can be used to enhance bioavailability. Valganciclovir is widely used as a prophylaxis against CMV infections.¹⁷ However, a meta-analysis demonstrated that valganciclovir for CMV prevention in solid organ transplant patients had no superior efficacy and significantly higher risk of absolute neutropenia, CMV late-onset disease, and CMV tissue-invasive disease compared to other standard therapies (e.g., valacyclovir, ganciclovir).⁵⁸ A recent study has suggested the safety and efficacy of valganciclovir for preemptive therapy and treatment of CMV disease in solid organ transplant recipients.⁵⁹

Foscarnet

Foscarnet is used most frequently in patients with CMV infection refractory to or intolerant of ganciclovir. Foscarnet also has activity against HSV and VZV, including acyclovir-resistant and ganciclovir-resistant strains. Although foscarnet and ganciclovir may have synergistic activity against CMV, there is no proven usefulness of their combination in therapy.⁶⁰ Use of the combination of ganciclovir and foscarnet is associated with greater toxicity than use of ganciclovir alone.⁶⁰ Foscarnet is available in an IV formulation only. Toxicity is common with foscarnet. Nephrotoxicity is a major dose-limiting side effect. Electrolyte abnormalities are also common, especially hypocalcemia, hypophosphatemia, hypomagnesemia, and hypokalemia, which may be symptomatic. Foscarnet may produce painful genital ulcerations; saline loading may diminish the likelihood of nephrotoxicity or genital ulceration.

Cidofovir

Cidofovir is a nucleotide analog that is active against many herpesviruses and other DNA viruses, including polyomaviruses, poxviruses, and adenovirus. It is active against acyclovir-resistant and ganciclovir-resistant HSV and CMV. Cidofovir is administered via IV once a week or once every 2 weeks. Its use is accompanied by high rates of nephrotoxicity. Neutropenia occurs in 20% of patients receiving this drug.

Ribavirin

Ribavirin has found wide use as part of a combination therapy for hepatitis C virus infection, but it is discussed here in the context of its use against other viruses. In vitro, ribavirin has activity against a wide range of DNA and RNA viruses. Ribavirin (aerosolized) is approved by the U.S. Food and Drug Administration (FDA) for the treatment of bronchiolitis and pneumonia due to respiratory syncytial virus. It has been used systemically in the treatment of some hemorrhagic fevers. Systemic ribavirin administration is associated with hemolytic anemia. Use of aerosolized ribavirin is controversial because of the drug's teratogenicity. Healthcare workers may potentially be exposed to the drug when it is used in conjunction with mechanical ventilation; use of aerosol containment systems are thus recommended.

Antiinfluenza Drugs

Amantadine, rimantadine, zanamivir, and oseltamivir are used in the treatment of influenza and for postexposure prophylaxis. Amantadine and rimantadine are active only against influenza A virus, whereas zanamivir and oseltamivir are active against influenza A and B viruses. In patients who have not received reduced doses of amantadine or rimantadine in the setting of renal dysfunction, serious neurotoxic reactions (including confusion and seizures) have been observed. Extensive experience with oseltamivir has been gained in recent years, and the drug has been found to be generally safe.

IV formulations of zanamivir or peramivir are now available on a compassionate-use basis for treating seriously ill patients, and peramivir was recently authorized for emergency use in hospitalized patients in the United States and licensed for use in Japan.⁴⁶ The efficacy of IV peramivir appeared to be similar to that of oseltamivir for seasonal influenza, but peramivir is less active for oseltamivir-resistant viruses than for oseltamivir-susceptible viruses. Thus IV zanamivir is the preferred option for seriously ill patients with suspected or documented oseltamivir resistance.⁴⁶

Acknowledgment

The contributions of Dr. Yoshiro Hayashi to a previous edition of this book are gratefully acknowledged.

KEY POINTS

1. For a generalized vesicular rash, scraping the base of the lesion and using polymerase chain reaction (PCR) to detect herpesviruses can assist in the rapid diagnosis of chickenpox or disseminated herpesvirus infections.
2. Cytomegalovirus (CMV) infection should be rapidly excluded as a cause of fever in an immunocompromised patient by way of detection of CMV DNA in peripheral blood by PCR.
3. Travelers from Africa, Asia, or South America who present with thrombocytopenia and fever should be assessed for Dengue and the viruses that cause hemorrhagic fevers. Strict contact isolation should be considered.
4. Herpes simplex virus (HSV), varicella-zoster virus (VZV), and enteroviruses can be detected by PCR of cerebrospinal fluid, enabling a rapid diagnosis.
5. Dosage adjustment is necessary for most commonly used antiviral agents in patients with renal dysfunction. Failure to adjust dosage may lead to adverse effects such as neurotoxicity.

Antibiotic-associated colitis was recognized soon after antibiotics were introduced in the 1940s, but the cause was not known until 1978 with the original reports of the role of *Clostridium difficile* as the agent in nearly all cases of antibiotic-associated pseudomembranous colitis (PMC) and ~20% of those with antibiotic-associated diarrhea. Subsequent work has identified the pathophysiology, epidemiology, diagnostic methods, and treatment for *C. difficile* infection (CDI).¹ CDI has emerged as a major challenge to healthcare systems, and it is also increasingly recognized as a community-associated pathogen.²⁻⁴ Prevention of CDI and the management of patients with multiple recurrences and life-threatening infections remain key areas for improvement.

ETIOLOGY

The consequences of *C. difficile* ingestion, usually as spores from contaminated hands, the environment, or possibly food, are varied. At one extreme the individual may simply excrete *C. difficile*, while at the other, life-threatening PMC with toxic megacolon may occur. In between these extremes, asymptomatic colonization (or carriage), diarrhea, or colitis may result. The mortality rate following CDI can be 15% to 20% (particularly for cases defined by the presence of free toxin; see below), which partly reflects the underlying comorbidities and frailty of many patients with this disease.⁵⁻⁷ There are occasional cases of antibiotic-associated colitis due to other pathogens (*Staphylococcus aureus*, *Klebsiella oxytoca*, enterotoxin-producing strains of *Clostridium perfringens*, or *Salmonella*), but most cases are either due to *C. difficile* or have no cause identified. Direct effects of antibiotics on gut peristalsis or the microbiome likely account for a considerable proportion of the remainder.¹

PATHOPHYSIOLOGY

There are six relevant issues:

1. Colonization with *C. difficile*: this organism is found in the colonic flora of 2% to 3% of healthy adults and 10% to 20% of hospitalized patients, which can increase further in long-stay elderly subjects.¹
2. Toxin production: *C. difficile* produces two toxins, A and B. Early studies implicated toxin A as the major enteric toxin based on animal studies that showed florid colitis with injection of toxin A into bowel loops. However, more recent studies established that toxin B is critical for clinical expression.⁸ Most strains of *C. difficile* produce both toxins, but about 1% to 2% produce only toxin B. Some strains also produce a binary toxin that may enhance virulence, but this remains controversial.^{9,10}
3. Antibiotic exposure: this is the most important identifiable risk and reflects the impact of the inducing agent on gut bacteria, typically reducing diversity and key components of the microbiome, which to date are poorly characterized. This creates an opportunity for *C. difficile*, already present in the gut or soon to be acquired, to convert from the spore to vegetative form, with replication and toxin production. Virtually every antibiotic has been implicated in CDI, but the most frequent culprits are clindamycin and broad-spectrum cephalosporins. *C. difficile* resistance to an antibiotic in some cases confers a selection advantage. For example, fluoroquinolones are also associated with increased CDI risk and may have promoted the emergence and selection of clones such as ribotype 027/NAP-1/BI,

which is significantly associated with poor outcome, including treatment failure, recurrence, need for surgical intervention, and mortality.¹¹⁻¹³ Notably, determining which antibiotic has caused CDI is problematic, as patients frequently receive multiple agents over weeks. Cumulative antibiotic exposure exponentially increases the risk of CDI.¹⁴

4. Epidemiology: *C. difficile* is relatively infrequent in ambulatory persons, but rates of colonization and disease are much higher as a result of exposure to the hospital environment. *C. difficile* now represents an important and potentially lethal nosocomial pathogen. Nursing homes are another setting in which there is clustering of vulnerable patients with high rates of antibiotic use where *C. difficile* may be endemic or epidemic.¹ In the period 2001-2006, the ribotype 027/NAP-1/BI strain emerged as an important epidemic agent of *C. difficile* in Canada, the United States, and Europe.^{3,11,15} This strain has declined in some countries (e.g., Western Europe and possibly North America) but is causing major problems in others (e.g., Germany, Eastern Europe).^{3,4,5,16}
5. Age: there is increasing susceptibility to the development of *C. difficile* colitis with age, possibly due to immunosenescence. However, age may simply be a proxy measure of multiple comorbidities that are known to exacerbate CDI risk.⁷
6. Immunologic susceptibility: patients may harbor toxigenic strains of *C. difficile* with no clinical expression despite extensive antibiotic exposure. One reason for this paradox is the apparent immune protection due to the presence of neutralizing antibody to toxins A and B. This observation accounts for the increasing interest in monoclonal antibodies to toxins A and/or B for treatment and in vaccines for prevention.^{1,17}

CLINICAL SIGNS AND SYMPTOMS

The typical presentation of CDI is watery diarrhea associated with cramps. Other common features are fecal leukocytes, endoscopy showing PMC or colitis, characteristic changes on computed tomography (bowel wall thickening restricted to the colon, often associated with ascites), fever, leukocytosis, and hypoalbuminemia (particularly in those with recurrent infections). Nearly all cases of CDI are associated with diarrhea, but paradoxically, patients with very severe cases may not have diarrhea because of ileus. An important indicator of CDI and its severity is the white blood cell (WBC) count; the average WBC is about 15,000 cells/mL, but it may be much higher, with counts over 20,000 or even 50,000 cells/mL. This strongly supports the diagnosis of CDI and predicts severe disease.¹⁸

DIAGNOSIS

Clinical diagnosis alone of CDI is unreliable, so laboratory testing of symptomatic patients is needed. The great majority of patients tested for CDI are not confirmed to have the illness. The diagnosis is based on detection of *C. difficile* (culture, enzyme immune assay [EIA] for glutamine dehydrogenase, or polymerase chain reaction [PCR] for toxigenic *C. difficile*) or its toxins (by EIA or cytotoxin assay). The most accurate way of diagnosing CDI is using a combination of tests that includes the detection of free fecal toxin.^{6,19} The relative merits of different testing methods are shown in Table 135-1.

TABLE 135-1 Diagnostic Tests for *Clostridium difficile* Infection

| TEST | WHAT DETECTED | TIME | ASSESSMENT |
|-----------------|---------------------------------|----------|--|
| Culture | <i>Clostridium difficile</i> * | 3-4 days | Nonspecific; uncommonly used in routine diagnosis. |
| Culture-toxin | Toxigenic <i>C. difficile</i> * | 3-4 days | Test for toxin after culture for clostridia; sometimes used in Europe. |
| Cytotoxin | Free toxin A/B | 2-3 days | Formerly gold standard, but slow and rarely used now in routine diagnosis. |
| EIA toxin A & B | Toxins A and B | Hours | Variable kit performance; not as sensitive as cytotoxin testing. False-positives do occur. |
| EIA GDH | <i>C. difficile</i> | Hours | Detects <i>C. difficile</i> but not specific; good screening test, particularly when used with a toxin test. Such algorithms are becoming the most common diagnostic method, especially in Europe. |
| Toxin B gene | Toxigenic <i>C. difficile</i> * | Hours | Detects toxigenic <i>C. difficile</i> ; sensitive. Has become widely used, especially in North America. However, use of these tests alone leads to overdiagnosis of CDI, notably as patients with diarrhea (due to another cause) may well be colonized by toxigenic <i>C. difficile</i> . |

*About 50% to 60% of *C. difficile* strains produce toxin. CDI, *Clostridium difficile* infection; EIA, enzyme immune assay; GDH, glutamine dehydrogenase.

TREATMENT

If possible, the implicated antibiotic(s) should be discontinued. If there is a need for continued systemic antibiotic treatment, a drug should be selected that is unlikely to cause CDI (e.g., narrow-spectrum β -lactams, macrolides, aminoglycosides, antistaphylococcal drugs, tetracyclines). There are three main choices at present for treatment of CDI: metronidazole, vancomycin, and fidaxomicin, all usually given by mouth.^{1,20} Metronidazole was often preferred because it is less expensive. However, recent evidence shows that oral vancomycin is superior to metronidazole. This has been demonstrated on an intention-to-treat basis²¹ and in severe CDI,¹⁹ usually defined as having a WBC over 15,000 cells/mL or elevated creatinine to $1.5 \times$ baseline.^{20,22} Other markers of serious disease are albumin less than 2 mg/dL, admission to the ICU for CDI, and PMC on endoscopy or radiologically.²³ Vancomycin is superior to metronidazole, likely because of its pharmacology. Vancomycin is not absorbed and so achieves higher sustained gut lumen concentrations than metronidazole. Fidaxomicin is also primarily nonabsorbed and has a similar initial cure rate to vancomycin, but it is associated with an approximate 50% reduction in recurrence rate compared with the latter (12% vs. 20%-25%).^{24,25} Fidaxomicin is considerably more expensive than vancomycin (or metronidazole), but it may be cost-effective for patients at increased risk of recurrence (e.g., patients with multiple comorbidities, those receiving concomitant systemic antibiotic therapy alongside CDI treatment, and those with recurrent CDI).^{26,27}

Variable proportions of recurrences are caused by relapse, typically within the first 2 weeks after treatment cessation, or reinfection. This likely reflects the continued deleterious effects of systemic antibiotics on the gut microbiome with superimposed changes caused by the drug used to treat the CDI. In such circumstances, persistent spore colonization may progress to germination and further toxin production with new onset of symptoms. Thus, narrower spectrum CDI therapeutics (such as fidaxomicin) are associated with less microbiome disruption or reduced diversity and hence a lower risk of recurrence.

Most patients improve with resolution of diarrhea in 3 to 5 days. Patients who are seriously ill (megacolon, septic shock, WBC > 30,000/mL, lactate > 5 μ M) and fail to respond to standard treatment should be considered for surgical intervention (colectomy or diverting loop ileostomy).^{23,28} Toxic megacolon markedly impairs delivery of vancomycin given orally to the site of infection. In such circumstances, vancomycin can be administered rectally via a catheter or enema. Although some patients are severely ill with signs of sepsis, it is perhaps surprising that bacteremia due to enteric bacteria is rare. *C. difficile* bacteremia as a complication of CDI has not been reported. Most seriously ill patients respond to standard management of sepsis, with particular attention to rehydration, while attempting to control disease with oral or rectal vancomycin and IV metronidazole with or without IV vancomycin.²⁹

Recurrence of CDI is a therapeutic challenge, especially in patients with multiple episodes. There is increasing use of fecal microbiota transplantation in such cases, delivered either via the mouth or rectum, with impressive reported efficacy.^{30,31} Screening of donors is necessary, and long-term safety remains a potential concern given the far-reaching effects of the gut microbiome.

There are several CDI treatment options in advanced clinical trials, including targeted antibiotics, a monoclonal antibody to toxin B, and tailored collections of gut microbiome-based bacteria.¹

PREVENTION

Prevention of *C. difficile* includes surveillance to detect increasing rates, emergent strain types, and outbreaks or epidemics; methods to prevent transmission of *C. difficile*; and strategies to prevent unnecessary exposure to antibiotics, especially those most likely to induce CDI.

It has long been believed that the great majority of CDI cases occurring in hospitals represents transmission of *C. difficile* from patients with the disease to at-risk recipient patients. However, a large, 3.5-year-study from the UK using highly discriminatory whole genome sequencing found that only 35% of all CDI cases were closely related to prior cases; less than a fifth (19%) were closely genetically related and involved hospital contact.³² Just under half (45%) of CDI cases in the study population were genetically distinct from all previous cases, which suggests that there is a large reservoir of strains causing infection. The modes of transmission and precise sources of the strains causing CDIs that are not closely linked to previous cases require further understanding. Possibilities include asymptomatic or transiently symptomatic *C. difficile* carriers, infants, food, and environmental niches.

The key measures to prevent horizontal transmission are hand hygiene with soap and water, barrier precautions, use of private rooms or cohorting of case patients as soon as they become symptomatic and until diarrhea resolves, and disinfection of environmental surfaces using sporicidal agents such as chlorine-containing agents or vaporized hydrogen peroxide. Patients with CDI should ideally have their own commode and room or be cohorted until diarrhea resolves. The decision to stop barrier precautions or transfer the patient should not be based on *C. difficile* testing, as there is no appropriate test to determine treatment response.

Avoidance of unnecessary antibiotic use with antibiotic stewardship programs is an important general practice principle and especially so in controlling CDI. When surveillance indicates an epidemic is occurring, it is important to define the associated antimicrobials. Published reports indicate control of epidemics through restraining or eliminating use of clindamycin, cefotaxime, or fluoroquinolones.²² Identification of the ribotype of the implicated strain may facilitate epidemiologic

investigations in outbreaks. However, this requires stool culture for *C. difficile*, which for most hospital laboratories requires referral of the strain to a typing reference center. One such system in the UK has been associated with a large decline in national CDI rates.³³

Investigational approaches to prophylaxis against CDI include vaccines and antibiotic sequestration or inactivation.¹

CONCLUSION

C. difficile has emerged as a major nosocomial pathogen that is usually associated with antibiotic use and that may cause a devastating colitis. It is optimally diagnosed by testing that includes the detection of fecal

toxin, and it usually responds rapidly to a combination of discontinuing the implicated antibiotic and adding oral vancomycin or fidaxomicin. Important issues for the intensivist in dealing with this nosocomial pathogen are (1) an understanding of the management guidelines for the patient with CDI who is critically ill and (2) the need for implementing careful infection-control procedures in all cases.

Acknowledgment

The author acknowledges the major contribution of John G. Bartlett to the field of *C. difficile* infection and, as the original author of this chapter, to the present discussion specifically.

KEY POINTS

1. Most cases of healthcare-associated infective diarrhea are caused by *C. difficile*.
2. Major complications of CDI are severe disease with ileus or toxic megacolon, sepsis, and recurrent disease.
3. Risks for CDI are advanced age, multiple comorbidities, exposure to antibiotics, and being in a hospital or chronic care facility. Antibiotics with the greatest risk are fluoroquinolones, second- and third-generation cephalosporins, and clindamycin.
4. The preferred diagnostic approach for CDI is a combination of a screening test (e.g., EIA to detect glutamine dehydrogenase or PCR to detect toxigenic *C. difficile*) plus a direct toxin detection test.
5. The usual management of CDI is to (a) discontinue the implicated antibiotic, (b) treat with oral vancomycin or fidaxomicin, and (c) maintain contact precautions to avoid nosocomial spread.
6. The ribotype 027/NAP-1/BI strain became epidemic in North America and Europe in the early to mid-2000s. This strain is promoted by fluoroquinolone use and causes severe disease, contributing to the increasing rates of CDI and mortality.
7. The intensivist is likely to see CDI as complication of antibiotic use in seriously ill patients; treatment is usually straightforward if the diagnosis is considered.
8. The intensivist may also see complicated cases, with critical disease indicated by a leukemoid reaction, renal failure, sepsis, ileus, or megacolon. These patients may require IV metronidazole, rectal vancomycin, and consideration of surgical intervention.

This important large, whole genome sequencing-based study challenged prior understanding about *C. difficile* transmission between CDI cases. It showed that the great majority of hospital-associated CDI cases cannot be directly linked to one another, with a large number of different strain types responsible, presumably entering the hospital from the community.

Anemia remains common in the critical care population, affecting more than 50% of patients at some point during their intensive care unit (ICU) stay. There are a multitude of causes of anemia including issues with losses and production that may be disease-related, patient-related, and even iatrogenic. This chapter will explore the problem of anemia in the euvolemic critically ill patient, its causes and effects, and the use and risk of red blood cell (RBC) transfusions in the management of this common problem with a focus on evidence-based studies. Particular emphasis will be placed on randomized controlled trials (RCTs) and systematic reviews, where available. The physiologic effects of anemia are covered elsewhere. A review of resuscitation practices and transfusion guidelines in patients suffering from hemorrhagic shock and/or trauma (i.e., the hypovolemic hemodynamically unstable patient) is also out of the scope of this chapter.

ANEMIA

According to the World Health Organization (WHO), anemia is defined as a hemoglobin level of <130 g/L in men and <120 g/L in nonpregnant women.¹ In the critical care population, modest anemia is generally accepted to be a hemoglobin level of ≤100 g/L in both men and women.

Epidemiology

Among all admitted ICU patients, the vast majority will experience an appreciable drop in hemoglobin. Large observational studies of this population have demonstrated the significance of this problem. In a 2006 European study of over 1000 sequential patients, anemia, as defined by a hemoglobin level of <130 g/L in men or <115 g/L in women, was observed in more than 80% of the patients, and by the time of discharge almost a quarter of them had a hemoglobin level of <90 g/L.² Similar observations were made in a 2004 North American critical care study that involved 4892 patients.³ In this report, 70% of the patients developed a hemoglobin level of <120 g/L within 2 days of ICU admission, and 50% had a hemoglobin level of <100 g/L.

Anemia develops early post ICU admission and on average within the first 2 days. In nonbleeding patients, an average hemoglobin drop of 5.2 g/L/day has been observed, with the largest decline seen in the first days following admission.⁴

Etiology

The significant drop in hemoglobin seen in ICU patients is the result of many factors, including problems with decreased production and increased losses. Production issues include a blunted erythropoietin response during critical illness, lack of substrate availability (including iron, vitamin B12, and folate), and the presence of renal failure (which may accentuate these but is also an independent risk factor of anemia).^{5,6} Anemia due to blood loss can be subdivided into disease-related and secondary causes. Disease-related causes of anemia include traumatic blood loss, coagulopathy, hemolysis, and gastrointestinal losses. Other secondary losses are primarily iatrogenic and include losses due to diagnostic sampling, vascular cannulation, renal replacement therapy, and surgical procedures. Daily diagnostic sampling can be an important contributor to anemia: when the average volume of blood taken per draw exceeds 10 mL, it results in an average of 40 mL of blood loss per day.⁷

Morbidity and Mortality Associated with Anemia

Although preclinical work has demonstrated that anemia becomes intolerated in healthy animals only under conditions of extreme hemodilution (hemoglobin concentration as low as 50 g/L),⁸ this is not necessarily true in humans. In a retrospective observational study of 300 consecutive anemic patients who declined RBC transfusion, no deaths were observed in those with postoperative hemoglobin levels between 71 and 80 g/L.⁹ However, in patients with postoperative hemoglobin levels between 41 and 50 g/L, mortality was 34%. Previous work in a similar population demonstrated that patients with a preoperative hemoglobin level of <60 g/L had significantly higher morbidity and mortality.¹⁰

Despite the theoretic rheologic benefits of hemodilution created during euvolemic anemia, cardiac output must increase to maintain oxygen delivery. This supply/demand balance is particularly stressed in the critically ill patient population where cardiac and peripheral oxygen consumption has increased. In patients with ischemic heart disease, coronary flow may be fixed, thereby creating a mismatch between blood supply and oxygen demand. In a large retrospective administrative database study of over 75,000 patients over the age of 65 with myocardial infarction, lower hematocrit (Hct) levels were associated with significantly higher rates of shock and heart failure, in-hospital and 30-day mortality and increased length of hospital stay.¹¹ These results should be interpreted with caution as retrospective studies are often limited by confounding factors.

Summary of Anemia Epidemiology and Clinical Impact

Anemia in critical care populations is common and is often caused by many simultaneous processes. Its physiologic effects impact not only oxygen delivery to vital organs and tissues but also increase cardiac workload as a consequence of natural compensatory mechanisms. These effects may be further accentuated in certain high-risk populations. Although anemia appears to be a risk factor for both morbidity and mortality, whether augmentation of hemoglobin levels with red blood cell transfusion can improve outcomes (and at what threshold this should occur) is less clear and is the focus of the discussion ahead.

RED BLOOD CELL TRANSFUSION

Epidemiology

Several large observational studies demonstrate that RBC transfusion is commonplace across ICUs in North America and Europe. In the American CRIT study,³ a cohort of 4892 patients from 284 ICUs in 213 hospitals were observed. Of these, 44% received at least one RBC transfusion during their ICU admission, with a mean pretransfusion hemoglobin level of 86 g/L (±1.7 g/L). This was similar to the European ABC Study (3534 patients, RBC transfusion rate 37%)⁷ and, more recently, a Scottish observational study involving 1023 sequential ICU admissions, where RBC transfusions occurred in 39.5% of patients.²

In the euvolemic critically ill patient, improving oxygen delivery is the most common reason for administering an RBC transfusion.¹² Specifically, in the CRIT study,³ low hemoglobin, active bleeding, and hemodynamic instability/hypotension were the most common

indicators for transfusion (90%, 24%, and 21%, respectively). These observations were consistent with the findings of the European ABC study,⁷ where active bleeding (56%) and anemia with diminished physiologic reserves (28%), altered tissue perfusion (17%), or ischemic heart disease (8%) were the most common reasons for transfusion.

Physiologic and Oxygen Transport Effects of RBC Transfusion

The negative effects of anemia on oxygen delivery, as described above, are clear. Although the improved delivery of oxygen following RBC transfusions in these patients has been demonstrated in several studies, an increase in oxygen uptake and consumption by the end organs and tissue beds is less evident and is not a consistent finding.

It is thus evident that despite a strong physiologic rationale to treat anemia in critically ill patients, particularly those with evidence of end-organ ischemia, studies have failed to demonstrate reliable benefits with respect to oxygen utilization. Furthermore, there are risks associated with RBC transfusions, and these risks are summarized in the next section.

Risks

Risks from RBC transfusions can result from infectious and non-infectious complications (Table 136-1). Complications from massive transfusions, including coagulopathies, electrolyte disturbances, acid-base imbalances, temperature dysregulation, and citrate toxicity are also of significant importance but are beyond the scope of this chapter.

Infectious Complications

Due to significant enhancements in donor screening and blood testing, the direct transmission of infection through contaminated blood supply is exceedingly rare and presented in Table 136-1.

TABLE 136-1

Complications Associated with Allogeneic RBC Transfusion

| | COMPLICATION | RISK PER RBC UNIT TRANSFUSED |
|-----------------------------|---|------------------------------|
| Infectious complications | Symptomatic bacterial sepsis | 1:250,000 |
| | Death from bacterial sepsis | 1:500,000 |
| | Hepatitis: | |
| | A | 1:2 million |
| | B | 1:153,000 |
| | C | 1:2.3 million |
| | HTLV | 1:4.3 million |
| | HIV/AIDS | 1:7.8 million |
| | West Nile virus | <1:1 million |
| | Parasitic infection | 1:4 million |
| Noninfectious complications | Urticarial reaction | 1:100 |
| | Febrile nonhemolytic reaction | 1:300 |
| | Transfusion-associated circulatory overload | 1:700 |
| | Transfusion-related acute lung injury | 1:10,000 |
| | Delayed hemolytic transfusion reaction | 1:7000 |
| | Acute hemolytic transfusion reaction | 1:40,000 |
| | Anaphylactic reaction | 1:40,000 |
| | Posttransfusion purpura | Rare |

AIDS, acquired immune deficiency syndrome; HTLV, human T-cell lymphotropic virus; HIV, human immunodeficiency virus; RBC, red blood cell

(Data from Callum JL, Lin Y, Pinkerton PH, et al. *Bloody Easy 3: blood transfusions, blood alternatives and transfusion reactions: a guide to transfusion medicine*. 3rd ed. Ontario Regional Blood Coordinating Network. 2011.)

Noninfectious Complications

Noninfectious complications of RBC transfusions are far more common (see Table 136-1). These represent a spectrum from relatively benign (fever) to more severe (acute lung injury) and imminently life-threatening (hemolytic reactions).¹³ The exact mechanisms by which these occur are not understood but are likely at least in part attributable to host immune and inflammatory responses. Central to immune-mediated reactions are donor interleukins and the tumor necrosis factor as well as antibodies or activated neutrophils, fragments of cellular membranes, and soluble human leukocyte antigen, which play important roles in transfusion-induced immunomodulation (TRIM). TRIM is purported to predispose patients to infections and cancer recurrence.¹⁴⁻¹⁶ Many Western countries across Europe and North America have adopted leukoreduction programs to reduce the effects of TRIM. TRIM may facilitate indirect infectious complications from RBC transfusions like healthcare-associated infections that occur downstream from the point of transfusion.

Evidence from Systematic Reviews. A recently published systematic review and meta-analysis (20 randomized trials, 7456 patients, published 2014)¹⁷ evaluated the risk of healthcare-associated infections linked to RBC transfusions and compared different transfusion strategies (liberal vs. restrictive strategy). They found that although a restrictive transfusion strategy was not significantly associated with fewer overall healthcare-associated infections, there was a significant risk reduction in serious infection rates (defined by the specific trials themselves) even when controlling for leukoreduction (number needed to treat 48, 95% CI: 36-71). Interestingly, this significance was not observed in a subgroup analysis of critically ill patients (2 studies, 1475 patients, $P = 0.104$). A systematic review of randomized trials to study the effect of restrictive versus liberal transfusion strategies to guide RBC transfusions was conducted by the *British Medical Journal*, a subgroup meta-analysis of 8 trials deemed lower risk of bias by the authors (5107 patients). The authors also showed a lower associated risk of infection with a restrictive transfusion strategy (RR 0.73, 95% CI: 0.55-0.98).¹⁸

In modern medicine, changes in donor screening and blood testing have led to a significant decline in direct RBC transfusion-related infections over the past 30 years. The leading cause of RBC transfusion-related morbidity and mortality is from transfusion-related acute lung injury (TRALI). The clinical picture of TRALI is difficult to distinguish from other causes of acute lung injury (ALI). A definite diagnosis of TRALI requires (1) no pretransfusion evidence of ALI; (2) new ALI occurring during or within 6 hours of RBC transfusion; and (3) no other likely direct or indirect confounding causes for lung injury.¹³ Given these strict diagnostic criteria and the fact that in the critically ill there are often confounding causes for ALI, the clinical importance of this complication is likely underestimated.¹⁹ This pathophysiologic process is secondary to increased lung endothelial permeability to inflammatory mediators and fluid, as a result of neutrophil activation in the recipient brought on by donor antibodies. A significant association has been found between the incidence of TRALI and the use of female donor plasma, particularly from female donors post pregnancy, as a result of increased human neutrophil antibodies.^{19,20} Incidence of TRALI has decreased since policy changes use male-only donated plasma.²¹

Complications Related to Age of Blood

Red blood cell storage encompasses the numerous physiologic and morphologic changes that occur in RBCs during storage, over time, and potentially as a consequence of the medium in which they are stored.²² These include biochemical changes such as a depletion of 2,3-DPG (causing a reduction in oxygen unloading), and adenosine triphosphate (intracellular energy stores), S-nitroso hemoglobin, and calcium. Biomechanical changes include membrane phospholipid loss and redistribution, protein oxidation and lipid peroxidation, release of free hemoglobin, and microvesicle formation, which lead to RBC membrane deformation, changing the typical biconcave

shape to permanently deformed spherocytocytes.²³ Consequently, the rheologic properties of blood are altered, potentially affecting the normal passage of these deformed RBCs through the capillary microvasculature.

The effect of the age of blood on clinical outcome has been reported in several observational studies, suggesting potential harm associated with older blood. These findings, however, were not validated in more rigorous study designs.

Evidence from RCTs. The Canadian-led Age of Blood Evaluation (ABLE) international randomized trial (published 2015) was conducted to study the effect of blood storage time on clinical outcome. ABLE included 2430 patients from 64 centers across Canada and Europe and tested the effect of transfusion of fresh (stored <8 days) RBCs compared to standard-issue RBCs (oldest available compatible blood) on 90-day mortality and clinically important morbidity.²⁴ The investigators found no significant difference in the primary outcome of 90-day mortality among those patients who received fresh RBCs (mean age 6.1 ± 4.9 days) compared to those who received the older units (mean age 22.0 ± 8.4 days). Further, there were no appreciable differences between the two groups in all of the secondary outcomes including major illnesses, duration of life supports (respiratory, hemodynamic, and renal), and length of hospital stay or transfusion reactions.

We await the results of a similar study currently being conducted by an Australian group called the TRANSFUSE-RCT (standard issue transfusion versus fresher red blood cell use in intensive care) (NCT01638416). In this large multicenter study, the investigators are aiming to recruit 5000 ICU patients to test the effect of transfusion of the freshest available versus the oldest available RBC and its effect on 90-day mortality.

RBC TRANSFUSION THRESHOLDS IN THE CRITICALLY ILL AND THE EVIDENCE-BASED STUDIES TO SUPPORT THEM

Evidence from Observational Studies

There are a multitude of observational studies examining the use of, indications for, and potential benefit or harm of RBC transfusions in several euolemic nonbleeding critical care populations.

Evidence from Systematic Reviews of Observational Studies. A 2008 systematic review of 45 of these observational studies demonstrated an association between RBC transfusions and poor outcomes including an increased risk of death, infection, organ dysfunction, and acute respiratory distress syndrome.²⁵ More recently, a systematic review of large-scale observational studies of mixed medical, surgical, ICU, and trauma patient populations (minimum 1000 patients) published between 2006 and 2010 demonstrated that RBC transfusions (as compared to no transfusion) were associated with adverse events, including mortality.²⁶ All of these studies, however, are subject to potential bias (most frequently the inability to effectively adjust for confounding by indication) significantly limiting the interpretation and generalization of the results.

Evidence from Randomized Controlled Trials

In guiding RBC transfusions of the critically ill, the rigorously designed TRICC trial remains the most influential.²⁷ This RCT included 838 ICU patients with a hemoglobin concentration of ≤ 90 g/L within 3 days of admission who were randomized to either a restrictive or liberal (70 g/L vs. 100 g/L) transfusion threshold strategy. The investigators found no significant difference in 30-day mortality between the groups (18.7 vs. 23.3%, $P = 0.11$). Further, subgroup analyses showed that 30-day mortality was significantly lower in the less sick subpopulation (patients with an APACHE II score of <20) and in those critically ill patients who were less than 55 years of age.

Evidence from Systematic Reviews. Several systematic reviews of randomized trials of RBC transfusion in critical care and other

populations exist. A comprehensive 2012 Cochrane Systematic Review by Carson et al.²⁸ examined transfusion thresholds and other strategies to guide transfusion (19 RCTs). A restrictive transfusion strategy significantly decreased the exposure risk for RBC transfusion. Although the authors found that a restrictive RBC transfusion threshold was associated with reduced hospital mortality (5 studies, RR 0.77, 95% CI: 0.62-0.95), no statistical significance was observed for 30-day mortality (11 studies, RR 0.85, 95% CI: 0.70 to 1.03). Furthermore, there was no statistically significant reduction in medical complications including pneumonia (5 studies), pulmonary edema (5 studies), stroke (5 studies), cardiac (7 studies), or venous thromboembolic events (3 studies). The authors also noted the lack of literature to guide transfusion practices in certain patient populations like those with acute cardiac ischemia. More recently, a systematic review of restrictive versus liberal transfusion strategies for RBC transfusion by Holst et al. included 31 trials from a number of different clinical settings.¹⁸ They concluded that a restrictive strategy resulted in less RBC transfusion and was not associated with less risk of death, either overall or in any of the population subgroups (Fig. 136-1). Differences in overall mortality or fatal or nonfatal myocardial ischemia were also not observed.

This suggests that a restrictive RBC transfusion strategy leads to fewer transfusions, decreasing exposure risks, and appears to not be associated with worse clinical outcomes and may in fact result in better outcomes as compared to a liberal transfusion strategy. Although a liberal RBC transfusion strategy has not been shown to be beneficial, certain critical care populations were either minimally or not included in these studies. The effect of such strategies on these subpopulations has remained in question.

TRANSFUSION THRESHOLDS FOR SPECIFIC SUBPOPULATIONS

There are certain critical care subpopulations with distinct physiology or pathophysiologic processes that are underrepresented in the trials discussed above, limiting the generalization of the existing evidence to guide their anemia management with RBC transfusions. A specific focus on septic shock, cardiac ischemia, and neurocritical care follows.

RBC Transfusion Thresholds in Septic Shock—Evidence from RCTs

A more liberal approach to RBC transfusions was suggested in septic shock patients with evidence of hypoperfusion/end-organ ischemia. This was based on the significant effect on survival when introduced as part of an early goal-directed therapy bundle demonstrated in the Rivers et al. RCT ($n = 263$, published 2001).²⁹ In this study, a target Hct $>30\%$ as part of a bundle of care was pursued in a specific subset of patients (depending on each patient's course through the treatment algorithm). Although 68% of patients in the intervention arm received an RBC transfusion, it was administered according to a bundle of care. As such, the direct effect of transfusion strategy on outcome cannot be ascertained. Interestingly, since then, two other RCTs of a goal-directed therapeutic approach to patients with severe sepsis/septic shock ($n = 1341$ and 796 , both published 2014), using similar strategies as the one published by Rivers et al., failed to demonstrate the same survival benefit.^{30,31} Transfusion rates in the intervention arm of both of these studies were under 15%.

The specific effect of transfusion strategies on outcome in septic shock has recently been tested (liberal vs. restrictive) in the TRISS RCT (published 2014).³² In this multicenter RCT of 1005 ICU patients, the effect of a liberal (Hb trigger <90 g/L) versus a restrictive (Hb trigger <70 g/L) transfusion strategy in patients with septic shock on 90-day mortality was examined. They found no appreciable difference in the primary outcome between the two groups (RR 0.94, 95% CI: 0.78-1.09) as well as no significant difference in ischemic events or use of life supports. Similarly, no important differences were found in subgroup analyses for age, chronic cardiovascular disease history or illness severity. It can thus be concluded that in septic shock patients,

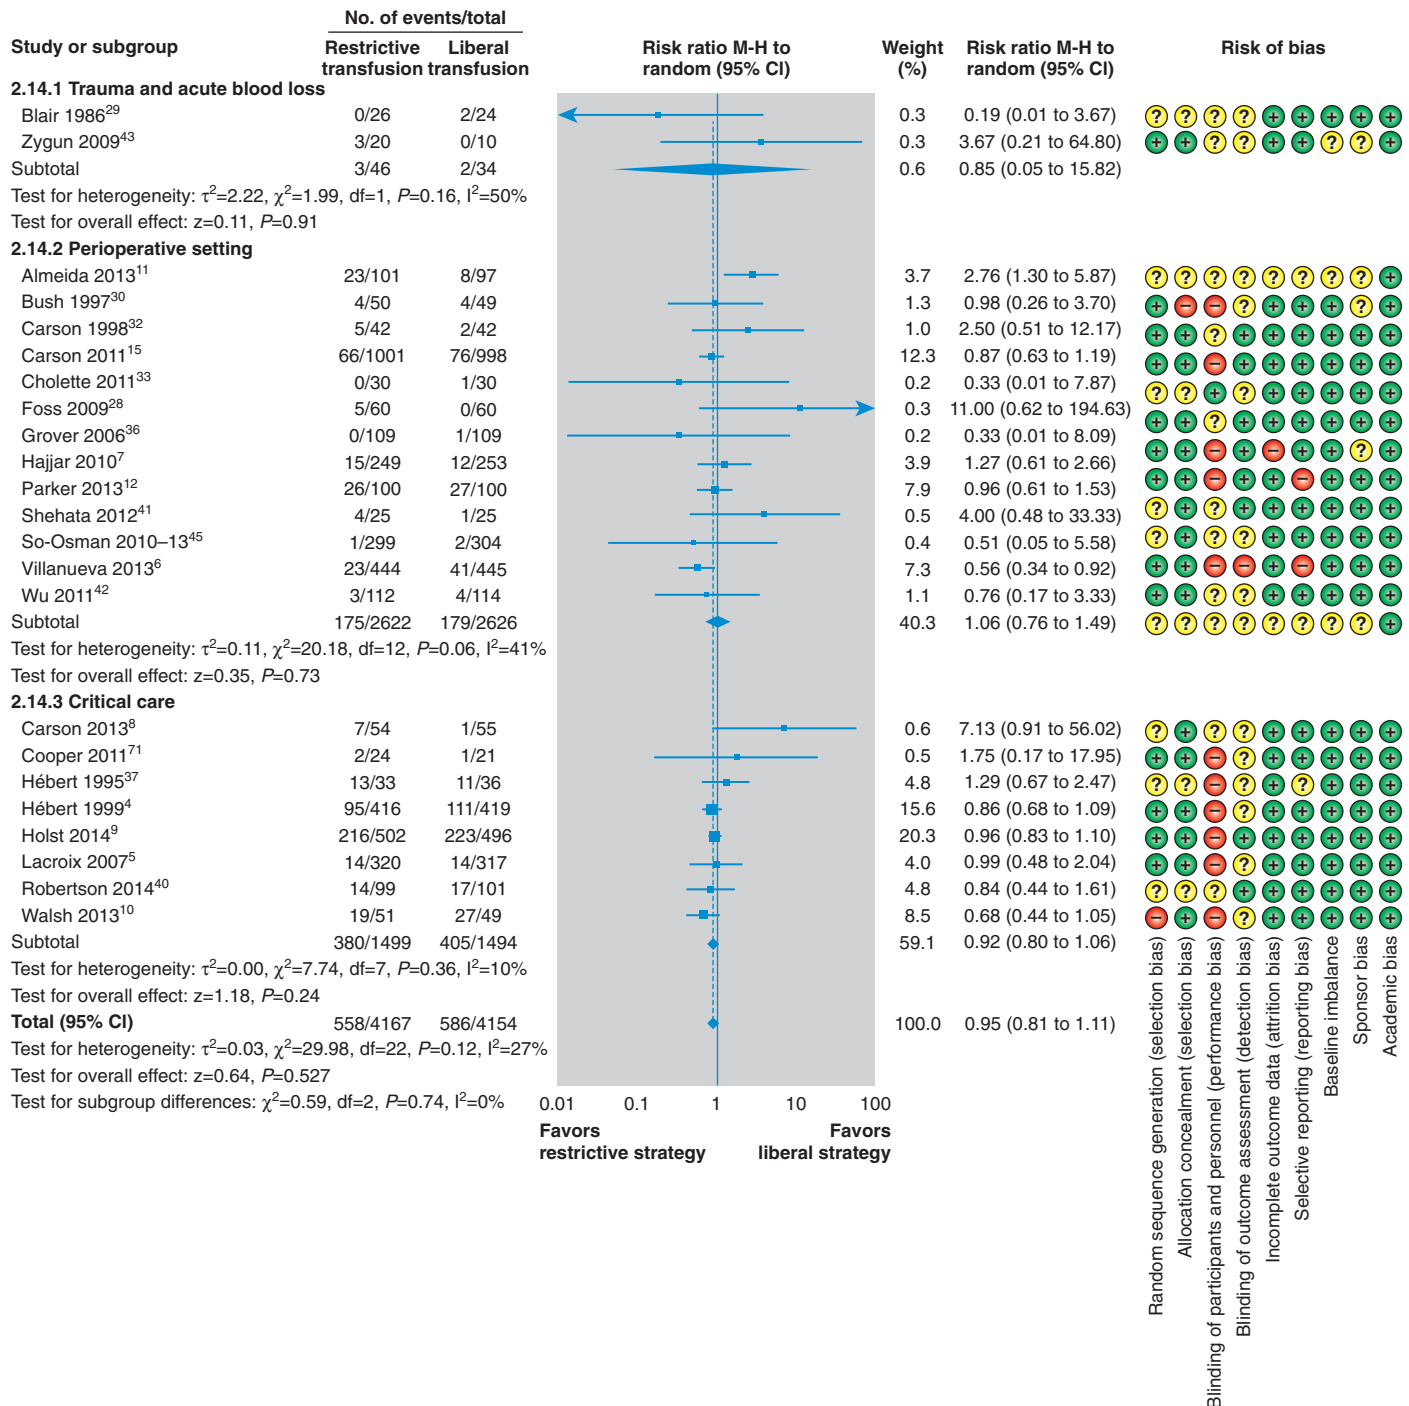

FIGURE 136-1 ■ Forest plot of the effect of restrictive versus liberal transfusion strategy on mortality stratified by patient population, presented as risk ratios with 95% confidence intervals and presented with risk of bias assessment. The size of square represents the weight of the trial in the pooled analysis. (From Holst L, Petersen M, Haase N, Perner A, Wetterslev J. Restrictive versus liberal transfusion strategy for red blood cell transfusion: systematic review of randomised trials with meta-analysis and trial sequential analysis. *BMJ* 2015;350:h1354.)

a restrictive strategy imparts no increased risk of mortality or negative outcome over a liberal strategy but is associated with fewer RBC transfusions. Indeed, the most recent edition of Surviving Sepsis Guidelines suggests a hemoglobin transfusion trigger of <70 g/L “once tissue hypoperfusion has resolved and in the absence of extenuating circumstances.”³³

RBC Transfusion Thresholds in Patients with Ischemic Heart Disease—Evidence from RCTs

As described above, the increased oxygen demands placed on the heart in the face of anemia may not be met by supply, propagating ischemic

processes. In a subgroup analysis of patients with cardiovascular disease ($n = 357$) enrolled in the TRICC trial,³⁴ no significant difference in clinical outcome (including hospital and 30-day mortality and length of stay) were found between the restrictive (Hb trigger of 70 g/L) and liberal (Hb trigger of 100 g/L) transfusion strategies. An insignificant trend toward harm (increased mortality) in the restrictive strategy group was observed in those patients with severe ischemic heart disease ($n = 257$).

This finding was challenged in the more recent FOCUS RCT (published 2011) of high-risk patients undergoing hip surgery ($n = 2016$, patients ≥ 50 years of age with a history of or risk factors for cardiovascular disease) randomized to either a restrictive (Hb trigger of 80 g/L) or a liberal (Hb trigger of 100 g/L) transfusion strategy.³⁵ The investigators found no difference between the groups for the primary outcome of death or inability to walk across the room without human assistance at 60 days. However, in a higher risk population of patients with acute coronary syndrome or stable angina undergoing angiography, a small pilot RCT³⁶ ($n = 110$, published 2013) of a restrictive (Hb trigger < 80 g/L) versus a liberal (Hb trigger < 100 g/L) transfusion strategy, a trend toward a decrease in the primary composite outcome of death, myocardial infarction, or unscheduled need for revascularization at 30 days was observed in the liberal strategy group (risk difference: 15.0%, 95% CI: 0.7-29.3%, $P = 0.054$).

Evidence in RBC transfusion strategies in the cardiovascular surgery population is more conflicting. In the TRACS noninferiority trial³⁷ ($n = 502$, published 2010), involving patients who had undergone cardiac surgery, a restrictive ((Hct) trigger $< 24\%$) compared to a liberal (Hct trigger $< 30\%$) transfusion strategy was noninferior with respect to their primary composite outcome of 30-day all-cause mortality and severe morbidity (10% vs. 11%). Most recently, a large multicenter RCT of patients aged 17 years or older and undergoing nonemergency cardiac surgery ($n = 2007$, TITRe2 trial published 2015) examined the effect of a liberal (Hb trigger < 90 g/L) versus restrictive (Hb trigger < 75 g/L) transfusion strategy on a composite of serious infections or ischemic events (including heart, brain, gut, or acute kidney injury) at 3 months.³⁸ Although there was no significant difference in the primary outcome between the two groups, a significant increase in mortality was observed in the restrictive arm (hazard ratio 1.64, 95% CI: 1.00-2.67, $P = 0.045$). Although the authors are careful to not overinterpret these secondary findings, they strengthen the call for further large pragmatic trials in this population.

A review of these findings support the claim that not all critical care populations are the same and that there may exist higher risk populations in which a restrictive transfusion strategy may not be safe, and potentially harmful, compared to a liberal strategy. There is an ongoing need for further study.

RBC Transfusion Thresholds in Neurocritical Care Patients—Evidence from RCTs and Systematic Reviews

The decreased oxygen delivery associated with anemia may have more significant effects on the brain injury population, including those patients with stroke, traumatic brain injury, and subarachnoid hemorrhage (SAH). Evidence to guide RBC transfusions in these populations is lacking, and whether obtaining a higher hemoglobin value is beneficial has not been adequately tested. In the TRICC trial, only 67 patients with a primary neurologic diagnosis were included in the original trial.²⁷ A subgroup analysis of these limited patients showed no difference in outcome between the liberal and restrictive transfusion strategies.³⁹

A recent systematic review of comparative studies of RBC transfusion in a neurocritically ill population (6 studies, no meta-analysis, published 2012)⁴⁰ found only one additional small RCT in an adult population (in addition to the subgroup analysis of TRICC presented above). This small RCT included 44 patients with SAH who were

randomized to either a liberal (Hb trigger of < 115 g/L) or a restrictive (Hb trigger < 100 g/L) RBC transfusion strategy.⁴¹ The study was underpowered to detect any clinically relevant outcome and used triggers that are higher than those currently practiced, which resulted in the majority of the patients receiving at least one RBC transfusion in both arms. There are no RBC transfusion strategy trials specific to an ischemic stroke population. Consequently, the aforementioned systematic review concluded that insufficient information existed to guide clinical practice.⁴⁰

Since this systematic review, a factorial design RCT of 200 patients with traumatic brain injury was published (2014).⁴² It aimed to test the effect of 2 hemoglobin transfusion threshold strategies (a liberal vs. a restrictive strategy—Hb thresholds of 100 g/L and 70 g/L, respectively) and erythropoietin versus placebo on favorable outcome as measured by the Glasgow Outcome Scale (GOS) at 6 months. No statistically significant difference between the two transfusion strategy groups was found ($P = 0.28$), but fewer thromboembolic events in the restrictive threshold group were reported (OR 0.32, 95% CI: 0.12 to 0.79). This study does not completely answer the clinical question of utility of liberal transfusion strategies in this patient population, as the study was underpowered to detect smaller yet clinically important outcome differences between the two transfusion groups (the study was powered to detect a 20% absolute increase in favorable outcome (GOS score) in the liberal transfusion arm compared to the restrictive arm). Further, although RBC transfusion rates differed in the two groups, the difference in median hemoglobin level was less than 20 g/L by day 9 (first data points presented) and increasingly smaller by days 16, 23, and 30.

Although these studies do not demonstrate specific harm by maintaining a restrictive transfusion strategy, it remains unclear if any benefits result from a more liberal strategy in these unique patient populations. Further rigorous study with RCTs is needed.

CONCLUSIONS—SUMMARY OF RBC TRANSFUSION THRESHOLD EVIDENCE AND PRACTICAL STRATEGY

Given the current evidence that exists to guide RBC transfusion strategies in the critically ill, it seems evident that in most populations a restrictive practice imparts no specific harm and may even be better than a liberal RBC transfusion strategy. As such, in the hemodynamically stable, euvolemic ICU patient, a transfusion hemoglobin trigger of 70-80 g/L is optimal. Careful consideration to individual cases must be taken in specific populations, including patients with cardiovascular disease and brain injury in which there is a need for more evidence to guide whether a more liberal strategy may be more appropriate.

KEY POINTS

1. Anemia is common in ICU and may negatively affect organ function and patient outcome.
2. RBC transfusions may improve oxygen delivery but not necessarily oxygen utilization and are not without significant risk.
3. In most hemodynamically stable critically ill populations, a restrictive RBC transfusion strategy (hemoglobin trigger of 70-80 g/L) is at least as good as and perhaps better than a liberal strategy.
4. Certain subpopulations of the critically ill such as those with cardiac or neurologic disease may benefit from a more liberal trigger, but further research is still needed.

This article evaluates the literature on the efficacy of RBC transfusions in the critically ill. It concludes that RBC transfusions do not improve tissue oxygen consumption consistently in critically ill

patients; it is not associated with improvements in clinical outcome and may result in worse outcomes in some patients. Specific factors that identify patients who will improve from RBC transfusions are difficult to identify, and lack of efficacy of RBC transfusions likely is related to storage time, increased endothelial adherence of stored RBCs, nitric oxide binding by free hemoglobin in stored blood, donor leukocytes, host inflammatory response, and reduced red cell deformability. Taken together, these studies generally support conservative RBC transfusion strategies in critical care to reduce the risk of transfusion-related adverse effects.

Blood component therapy has had a central role in the development and practice of numerous medical advances, especially in modern surgery. It is only in more recent years that blood transfusion is no longer regarded as essential for a wide range of medical and surgical conditions.¹ It is now possible for most uncomplicated major surgery to be conducted without allogeneic blood component therapy. *Blood component transfusion* is generally supportive therapy for the correction of one or more hematologic deficiencies until the basic disease process can be controlled or corrected. During the past decade there has been a shift from a donor focus to one of patient blood management in blood component therapy. Standard of care for the role of allogeneic blood component therapy in clinical medicine addresses the three-pillar matrix of patient blood management.² Attention to accurate diagnosis of the hematopoietic deficiencies, minimizing blood loss, and tolerance of deficiencies, within limits, is important. Before considering transfusion there should be appropriate consideration of the range of therapeutic options available and their potential hazards.³

Blood component therapy and its immediate endpoints are part of a medical management process. Although appropriate endpoints may be achieved in terms of measurable parameters or immediate clinical response, the clinician needs evidence that these traditional surrogate endpoints are relevant and correlate with clinical outcome for the patient. In many areas of transfusion medicine, evidence from prospective randomized trials is not available, and the clinician must base therapy on a good understanding of the problem in terms of pathophysiology and indicators of severity. Transfusion medicine decision making can be difficult, and there is ongoing debate regarding the indications for various allogeneic blood components.⁴ Unnecessary allogeneic transfusion can be avoided or minimized by giving attention to the clinical time frame, hematologic defect, alternatives, and knowledge about blood components and the potential hazards. The concept of transfusion alternatives can be challenged as inappropriate, as most of the so-called alternatives are indeed optimal patient management. There is now good evidence supporting a restrictive red cell transfusion policy in hemodynamically stable patients with hemoglobin levels above 7 gm/dL.^{5,6} In managing a patient's oxygen-carrying capacity, a three-pillar approach—optimizing red cell mass, minimizing blood loss, and tolerating anemia in the short term—results in avoidance of allogeneic transfusion in most uncomplicated elective surgical cases.² This can be achieved by identifying patients at high risk of bleeding, giving attention to surgical and anesthetic techniques (e.g., controlled hypotension, hypothermia prevention, reduction of venous pressure at the operative site), and using pharmacologic agents to minimize blood loss. Autologous methodologies including perioperative hemodilution, blood salvage, fibrin glue, and platelet fibrin gel may all have a part to play.

GUIDELINES FOR BLOOD COMPONENT THERAPY

The following is a brief summary of the guidelines for use of commonly available blood components. Fig. 137-1 illustrates the general approach to the decision to transfuse blood components, with the emphasis on patient blood management and how blood component therapy fits into a more comprehensive approach to clinical management. This move from a blood product focus to a patient focus

has resulted in the development of patient blood management guidelines.⁷

Red Blood Cell Concentrates

Appropriate and inappropriate use of red blood cell (RBC) transfusions in acute medicine has received considerable attention in recent years; however, identifying the benefits of RBC transfusion in many circumstances has been difficult.^{8,9} The question of the lowest safe hematocrit remains controversial. In an otherwise stable patient, the transfusion of RBC concentrates is likely to be inappropriate when the hemoglobin level is above 100 gm/dL. Their use may be appropriate when hemoglobin is in the range 70 to 100 gm/dL if there are other defects in the oxygen transport system. The decision to transfuse should be supported by the need to relieve clinical signs and symptoms of impaired oxygen transport and to prevent morbidity and mortality, ultimately to improve clinical outcomes. The transfusion of RBC concentrates is likely to be appropriate when hemoglobin is less than 70 gm/dL and the anemia is not reversible with specific therapy in the short term, but lower levels may be acceptable in patients who are asymptomatic, especially in the younger age group.

Platelet Concentrates

Prophylactic transfusion of platelet concentrates is indicated in patients with bone marrow failure when the platelet count is (1) less than $10 \times 10^9/L$ and there are no associated risk factors for bleeding or (2) less than $20 \times 10^9/L$ in the presence of additional risk factors. However, recent evidence suggests lower levels may be tolerated if there is no clinical evidence of hemostatic failure.¹⁰⁻¹²

In patients undergoing surgery or invasive procedures, the platelet count should be maintained at greater than $50 \times 10^9/L$. In patients with qualitative defects in platelet function, platelet count is not a reliable indicator for transfusion, and transfusion decisions and monitoring of efficacy should be based on the setting and clinical features. The wide use and increasing range of antiplatelet medications is a challenge, especially in the perioperative setting. The role of ex vivo point of care platelet function testing in predicting hemorrhage is promising.¹³

Platelet transfusions are indicated in hemorrhaging patients in whom thrombocytopenia is secondary to marrow failure and is considered a contributory factor to the bleeding. In massively hemorrhaging patients, platelet transfusions in conjunction with correcting plasma coagulation factor deficits are indicated when the platelet count is less than $50 \times 10^9/L$ or less than $100 \times 10^9/L$ in the presence of diffuse microvascular bleeding. The transfusion of platelet concentrates is not generally considered appropriate when thrombocytopenia is due to immune-mediated destruction, in patients with thrombotic thrombocytopenic purpura and hemolytic uremic syndrome, or in uncomplicated cardiac bypass surgery.

Fresh Frozen Plasma and Cryoprecipitate

Fresh frozen plasma is widely used, but there are limited specific indications for its use, and there is a dearth of evidence for efficacy in most clinical settings. The use of fresh frozen plasma may be appropriate in patients with a coagulopathy who are bleeding or are at risk of bleeding

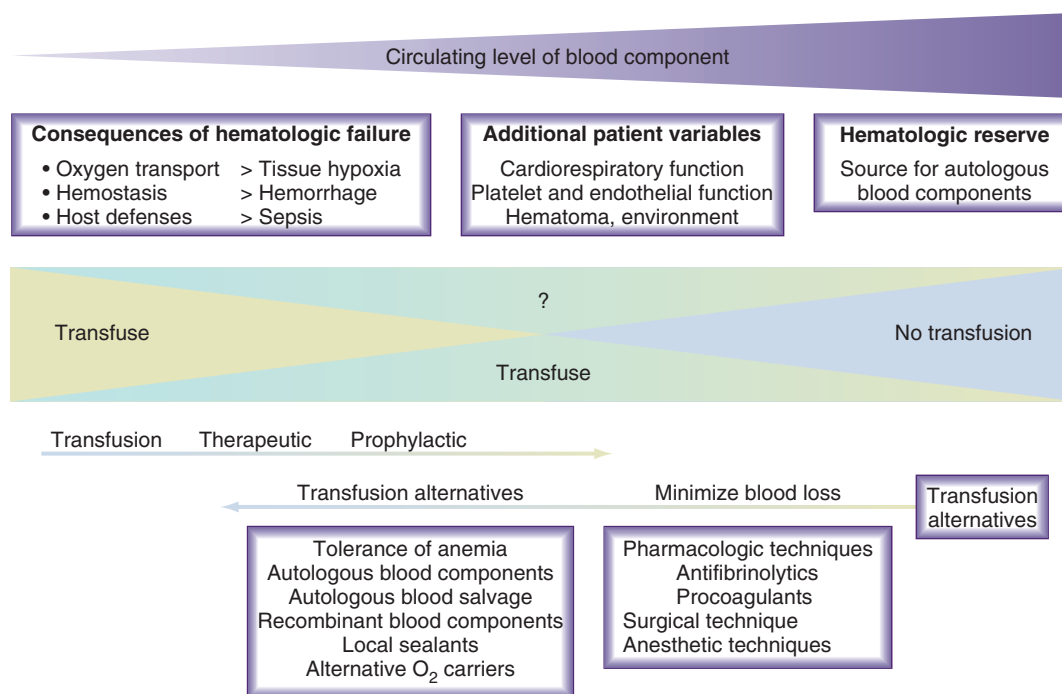

FIGURE 137-1 ■ Overview of blood management and where blood component therapy may be appropriate.

when a specific therapy or factor concentrates are not appropriate or are unavailable. Fresh frozen plasma is generally indicated in acutely hemorrhaging patients, usually as an inclusion in a massive transfusion protocol. There is poor evidence for the prophylactic use of fresh frozen plasma in many clinical settings.¹⁴⁻¹⁸ Fresh frozen plasma is rarely indicated in vitamin K deficiency or reversal of warfarin therapy, because concentrates are now generally available.^{19,20} The use of fresh frozen plasma is generally not considered appropriate in cases of hypovolemia, in plasma exchange procedures in treatment of immunodeficiency states, or prophylactically in nonbleeding coagulopathic intensive care unit (ICU) patients prior to invasive procedures.²¹

Cryoprecipitate contains factor VIII, fibrinogen, factor XIII, von Willebrand factor, and fibronectin and is principally indicated for fibrinogen deficiency or dysfibrinogenemia when there is clinical bleeding, invasive procedures, trauma, or acute disseminated intravascular coagulation (DIC).

Plasma-Derived Products

Table 137-1 summarizes commonly used fresh and plasma-derived blood products. Fibrinogen concentrate instead of cryoprecipitate is having an increasing role in the management of hypofibrinogenemic states, depending on local availability.

Recombinant Blood Products

Development and introduction of recombinant blood components continue to be one of the most exciting advances in transfusion medicine. Recombinant growth factors (cytokines) such as erythropoietin and granulocyte stimulating factor have had a major impact on managing anemia and neutropenia. There are further promising recombinant cytokines in development that could have a role in countless clinical conditions, especially as antiinflammatory and tissue-protecting agents. Recombinant hemostatic factors have improved the management of hemophilia. Recombinant activated factor VII (rFVIIa) was originally developed for treating hemophiliac patients with coagulation factor inhibitors. However, it is having an impact on the

management of a range of hemostatic disorders. Factor VIIa initiates the extrinsic coagulation pathway only when complexed to tissue factor at sites of injury. Its wider use has had a checkered history and although it may have a role in a range of hemostatic disorders, evidence in terms of safety and efficacy has been conflicting. It has been difficult to establish a sound evidence base outside the hemophilia setting for the use of rFVIIa, with most experience being observational and anecdotal.

Blood Substitutes

Efforts have been ongoing for many years to develop substitutes for RBCs and platelets, but results have been disappointing, and safety concerns have plagued clinical development.

TRANSFUSION MANAGEMENT OF MASSIVE ACUTE HEMORRHAGE

In recent years, there has been a reappraisal of guidelines for the use of blood components in acutely hemorrhaging patients.²² Guidelines are more focused on managing critical bleeding and avoiding the massive transfusion coagulopathy quagmire in which a patient spirals down into the “triad of death”: coagulopathy, acidosis, and hypothermia. Advances in patient retrieval, resuscitation protocols, techniques for rapid and real-time diagnosis, trauma teams, and early “damage-control” surgery have improved the management of acutely hemorrhaging patients. There is also greater attention and research being directed toward the nature of clear fluids and the importance of plasma viscosity, colloid oncotic pressure, and functional capillary density.

Patients are now surviving increasingly larger volumes of blood transfusion, but sepsis, acute lung injury, and multiorgan failure remain challenges. Although blood transfusion may be life saving for exsanguinating patients, it is increasingly recognized that transfusion may be an independent risk factor for delayed morbidity and mortality. Transfusion can be minimized with tolerance of hypotension until hemorrhage is controlled and lower hemoglobin levels are accepted. The immediate posttransfusion function of stored red cells and

TABLE 137-1 Blood Products

| BLOOD PRODUCT | MAIN INDICATIONS |
|--|---|
| Whole blood* | Rarely indicated in acute hemorrhage unless other blood products are unavailable |
| Red blood cell concentrates* | Hemorrhage and anemia |
| Leukocyte-depleted blood* | In patients having febrile reactions, to avoid leukocyte immunization in selected patients (especially patients with hematologic malignancy). Universal prestorage leukodepletion is more widely used and has the added benefit of minimizing storage lesions. |
| Platelet concentrates* | Thrombocytopenia due to marrow hypoplasia or platelet functional defect |
| Granulocyte concentrates* | Occasionally in patients with sepsis associated with profound and prolonged neutropenia secondary to marrow suppression |
| Fresh frozen plasma* | Specific or multiple plasma protein deficiencies (especially coagulation) |
| Cryoprecipitate* | Hypofibrinogenemia and rarely in factor VIII and von Willebrand disease, when concentrates are unavailable ³¹ |
| 4% or 5% albumin solutions† | Plasma volume expansion. Use is controversial, and the role of albumin solutions in critically ill patients remains under deliberation. ³² |
| Concentrated albumin† | Severe hypoalbuminemic states with complicating hypovolemia |
| Concentrate of coagulation factors II, VII, IX, and X† | Vitamin K–dependent factor II, IX, and X deficiency and reversal of oral vitamin K antagonists |
| Specific factor concentrates† | Factor VIII and IX concentrates have an established role in management of hemophilia, but others are in the process of establishing their clinical efficacy and indications. ^{26,33,34} Fibrinogen concentrates for hypofibrinogenemia and dysfibrinogenemia ²⁶ Antithrombin concentrates are available for thrombophilia due to antithrombin deficiency and are increasingly recommended in other disorders in which antithrombin may be depleted (e.g., DIC, MODS). ³⁵ |
| Gamma globulin† | Generally used intravenously for replacement in hypogammaglobulinemia or in high dosage as an immune-modulating therapy ^{36,37} |
| Specific immune gamma globulins† | Rhesus prophylaxis, specific infection prophylaxis and treatment ³⁸ |

†Fractionated plasma products.

DIC, disseminated intravascular coagulation; MODS, multiorgan dysfunction syndrome.

hemoglobin in delivering oxygen to the microcirculation and in oxygen unloading is also being questioned, with the storage age of RBCs possibly being associated with poorer clinical outcomes. Recent animal data point to the immediate clinical benefit of transfused red cells in treating hypovolemic shock relating more to reconstitution of the macrocirculation, with potentially adverse effects on the functional capillary density in the microcirculation.

A protocol approach to blood component therapy has been a controversial issue, with advocates for correcting hemostatic defects when they are identified and those for up-front protocol component therapy with fixed ratios of red cells, platelets, and fresh frozen plasma. The recent PROPPR randomized controlled trial compared equal numbers of fresh frozen plasma, platelets, and RBCs (1:1:1) to half as much fresh frozen plasma and platelets as RBCs (1:1:2). There was no significant difference in mortality at 24 hours or at 30 days, although

exsanguination in the first 24 hours, a secondary outcome, was significantly decreased in the 1:1:1 group versus the 1:1:2 group, and more patients achieved hemostasis. This is probably the best evidence available supporting a 1:1:1 ratio.²³ Ironically, as 1:1:1 is leukodepleted “reconstituted” whole blood, this raises the perennial question of the role for whole blood and fresh whole blood in the critical bleeding setting.²⁴

With better understanding of coagulopathy and the importance of hypofibrinogenemia and hyperfibrinolysis, there is a reanalysis of the approach to blood component therapy. Failure of hemostasis is common in acutely bleeding patients and may be complex and multifactorial. Accumulating evidence supports the view that the pathophysiology of coagulopathy, when occurring in the context of critical hemorrhage, should be viewed as related to the primary insult or initiating event. A secondary coagulopathy may compound the problem in the resuscitated patient, such as massive stored blood transfusion, hemodilution, hypothermia, and continuing tissue hypoxia. The primary mechanisms of coagulopathy relating to the initiating event may relate to trauma, hypoxia, pregnancy, sepsis, envenomation, or antithrombotic agents. In all circumstances there is activation or inhibition of some aspect of the hemostatic system, and therapy is better informed if these varied mechanisms are better understood. Frequently, complex tests are required for definitive diagnosis, but the urgency of the situation cannot always wait for the results, and therapy may be initiated on clinical evidence with minimal laboratory information.

Many trauma patients have coagulopathy at presentation related to hypovolemic shock and not consumption or dilution.²⁵ Activation of the protein C system and hypofibrinogenemia due to secondary hyperfibrinolysis are important. In the massively transfused patient, thrombocytopenia and impaired platelet function are the most consistent significant hematologic abnormalities, correction of which may be associated with control of microvascular bleeding. The level of fibrinogen is now recognized to be of greater importance than previously thought.²⁶ A problem with clotting time standard screening tests of coagulation function is that they do not provide information about the formation of the hemostatic plug, its size, structure, or stability. Global tests of hemostatic plug formation and stability such as thromboelastography are of increasing use. With ongoing bleeding and associated microvascular oozing, various approaches may be taken. Having ensured that all identifiable hemostatic defects have been corrected, questions then arise as to the role of fresh blood and recombinant activated factor VII.²⁷

HAZARDS OF ALLOGENEIC TRANSFUSION

Allogeneic blood transfusion is a tissue transplant that is probably associated with the greatest range of potential hazards of any medical intervention and should only be used in circumstances in which there is good evidence that clinical outcomes will be improved. The pathophysiology of transfusion reactions can be divided broadly into the following four categories. More detailed discussion of the complications of allogeneic blood transfusion are discussed in other chapters.

1. Reactions may occur due to *immunologic differences* between the donor and recipient, resulting in varying degrees of blood component incompatibility. In general, for a reaction to occur, the recipient needs to have been previously immunized to a cellular or plasma antigen.
2. A wide range of *infectious agents* may be transmitted by allogeneic blood component therapy.
3. *Alterations in blood products due to preservation and storage* may result in quantitative or qualitative deficiencies in the blood components that reduce transfusion efficacy and expose the patient to potentially adverse consequences from substances that accumulated during storage (Table 137-2).^{28,29}
4. *Clinical, technical, and clerical errors* resulting from incorrect patient identification, failure of cold chain management, or administration errors may result in a range of hazards. Included in this

TABLE 137-2

Red Blood Cell Storage Lesions and Possible Clinical Consequences

| STORAGE LESION | POTENTIAL CLINICAL CONSEQUENCES |
|---|---|
| Alterations in red blood cell structure and function | |
| ATP depletion | Echinospherocyte formation, increased osmotic fragility, impaired RBC deformability with adverse effects on oxygen transport and delivery |
| Microvesiculation and loss of membrane lipid, lipid peroxidation and hemolysis, and irreversibly damaged RBCs | Reduced RBC viability and cell death Hyperbilirubinemia, LDH, increased serum iron, free radical generation (?), hyperkalemia |
| Reduced 2,3-DPG | Increased hemoglobin affinity for oxygen and impaired unloading |
| Decreased CD47 antigen (integrin-associated protein) expression | Reduced posttransfusion survival due to premature clearance post transfusion |
| RBC adhesion to endothelial cells | Adverse effects on microcirculatory hemodynamics |
| Storage temperature | Hypothermia unless pretransfusion warming |
| Additives | |
| Citrate | Hypocalcemia, acid-base imbalance, initial acidosis alkalosis |
| Glucose | Hyperglycemia |
| Sodium | Hypernatremia |
| Cytokines: IL-1, IL-6, IL-8, TNF | Fever, hypotension, flushing |
| Enzymes: Myeloperoxidase, elastase, arginase, secretory phospholipase A ₂ | Transfusion-related immunomodulation, neutrophilia |
| Reactive proteins: Defensins, annexin, soluble HLA, Fas ligand, soluble endothelial cell growth factor, and others | Proinflammatory, potential “priming” for ARDS, TRALI, and MODS |
| Histamine and kinin accumulation | Hypotension, anxiety, flushing, pain syndromes, proinflammatory |
| Microaggregates and procoagulants | Blockade of reticuloendothelial system Risk factor for development of ARDS, MODS, TRALI Activation of hemostasis > DIC (?), VTE (?), arterial thrombotic events (?) |

ARDS, acute respiratory distress syndrome; ATP, adenosine triphosphate; DIC, disseminated intravascular coagulation; 2,3-DPG, 2,3-diphosphoglycerate; HLA, human leukocyte antigen; IL, interleukin; LDH, lactate dehydrogenase; MODS, multiorgan dysfunction syndrome; RBC, red blood cell; TNF, tumor necrosis factor; TRALI, transfusion-related acute lung injury; VTE, venous thromboembolism.

group are patients who are at particular risk from lung injury and circulatory overload due to comorbidities such as cardiac compromise, poor clinical assessment of fluid and volume status, and sepsis.

In terms of causation of an adverse clinical event, the possible role of transfusion can be classified broadly into three categories on the basis of probability³⁰ (Fig. 137-2). Hemovigilance programs focus on the adverse events that are included within categories 1 and 2 but do not address the question of the appropriateness of the clinical indication for the transfusion.

1. **Definite—unifactorial.** The well-understood and well-reported hazards of transfusion (i.e., immunologic, technical, infectious) are

generally unifactorial, with a 1:1 well-understood deterministic causal relationship between the blood component transfused (usually a specific individual unit) and the adverse consequence for the patient. ABO blood group incompatibility, transfusion-related infection transmission, transfusion-associated graft-versus-host disease, and transfusion-related lung injury due to donor leukoagglutinins are examples in this category.

2. **Probable—oligofactorial.** Some adverse consequences of transfusion result from interaction with other insults, pathophysiology, or host factors, but the contribution of the transfusion can usually be specifically identified in a deterministic manner. Fever, allergic reactions, hypotensive reactions, pulmonary edema, some cases of transfusion-related lung injury, hyperbilirubinemia, and cytomegalovirus transmission are examples of this category.
3. **Possible—multifactorial.** Transfusion may contribute to a complication or poor clinical outcome. In these circumstances, a causal implication for transfusion is probabilistic (i.e., a risk factor), and it is not necessarily the major factor. Transfusion-induced immunomodulation and the clinical consequences of storage lesions fall into this category.

Blood Storage Lesions and Potential Clinical Consequences

Blood is altered from the moment of its initial collection and subsequent storage. Physical and biochemical characteristics may be of particular importance when large volumes are infused rapidly. Warming of all rapid blood transfusions should minimize the possibility of hypothermia. Patients receiving massive blood component therapy are likely to be seriously ill and have multiple problems. Potential adverse effects must be considered in conjunction with the injuries and multiorgan dysfunction. It is not always possible to define complications caused or aggravated by massive blood transfusion.

The storage lesions progressively increase until the time of expiry, and the extent of these changes is determined by the specific blood component, preservative medium, container, storage time, and storage conditions. Storage results in quantitative and qualitative deficiencies in blood components, which may reduce the efficacy of a transfusion. Quantitative deficiencies may result in reduced RBC survival, failure to achieve anticipated endpoints, and excessive donor exposure, increasing immunization and infection risks. Qualitative deficiency includes decreased membrane flexibility and increased adhesion to endothelium, which may impair microcirculatory hemodynamics. Reduced 2,3-diphosphoglycerate decreases hemoglobin oxygen affinity, impairing oxygen unloading.

In parallel with these storage changes is an accumulation of degenerate material (e.g., microaggregates, microparticles, and procoagulant material), release of vasoactive agents, cytokine generation, and hemolysis (Fig. 137-3). Many of the changes occurring during storage are related to the presence of leukocytes (especially granulocytes) and can be minimized by prestorage leukoreduction. The clinical significance of storage lesions continues to be debated. In some cases, the effects are widely accepted; in others, further studies are needed. There is evidence that the storage lesion is clinically significant in several respects. Transfusion may result in significant increases in unconjugated bilirubin and lactic dehydrogenase, neutrophilia, and saturation of serum iron. The transfusion of biologically active lipids in stored blood may be associated with the development of acute lung injury in patients with predisposing conditions. Blood transfusion has been shown to be an independent risk factor for the development of postinjury multiorgan failure and acute respiratory distress syndrome, and this relationship may be stronger with the age of the transfused blood. There is an increased rate of infection associated with transfusion of old blood after severe injury, suggesting that transfusion-related immunomodulation may not be related only to allogeneic transfusion, but contributed to by the storage lesion. Further information about the storage lesion and the possible clinical implications is summarized in Table 137-2. Hyperbilirubinemia warrants a special mention.

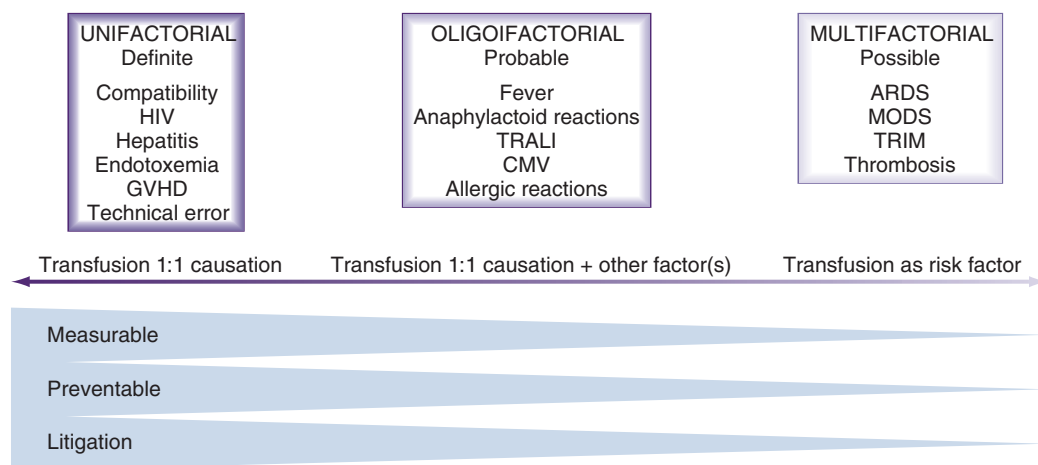

FIGURE 137-2 ■ Hazards of allogeneic blood transfusion. ARDS, acute respiratory distress syndrome; CMV, cytomegalovirus; GVHD, graft-versus-host disease; HIV, human immunodeficiency virus; MODS, multiorgan dysfunction syndrome; TRALI, transfusion-related acute lung injury; TRIM, transfusion-related immunomodulation.

FIGURE 137-3 ■ Red blood cell storage lesions. ARDS, acute respiratory distress syndrome; GIT, gastrointestinal tract; LDH, lactate dehydrogenase; MOF, multiple organ failure; RES, reticuloendothelial system; TRALI, transfusion-related acute lung injury.

Hyperbilirubinemia is common after massive blood transfusion because a significant proportion of RBCs transfused may not survive, and the resulting bilirubin load causes varying degrees of hyperbilirubinemia. If the patient has been hypovolemic and shocked, biliary transport functions may be impaired, particularly in the presence of sepsis or multiorgan dysfunction. An important rate-limiting step in bilirubin transport is the energy-requiring process of transporting conjugated bilirubin from the hepatocyte to the biliary canaliculus. Bilirubin from destroyed transfused RBCs may be conjugated, but delayed excretion may lead to conjugated hyperbilirubinemia. A hemolytic transfusion reaction and resorbing hematoma also have to be considered as possible causes of hyperbilirubinemia.

Allogeneic Transfusion as an Independent Risk Factor for Poorer Clinical Outcomes

In recent years, experimental and clinical studies have identified blood transfusion as an independent risk factor for morbidity and mortality as well as increased admission rates to ICUs, increased length of hospital stay, and additional costs. The implication of RBC transfusion as part of the problem rather than optimal therapy has challenged long-held views about the safety of allogeneic blood transfusion. It has generally been assumed that blood transfusion can only be of *benefit* to the bleeding or anemic patient, with immunologic and infection transfusion hazards well understood and minimized. There is increasing

evidence that transfusion-related immunomodulation (TRIM) and the transfusion effects of storage lesions may be responsible for poorer clinical outcomes in a range of clinical settings. There is also an association of transfusion with a higher incidence of venous thromboembolism. The case for the association between blood transfusion and poorer outcomes is strengthening, and evidence for the efficacy of many transfusions is being reassessed, as are studies supporting restrictive red cell transfusion policies as not jeopardizing clinical outcomes. Until these concerns are resolved, a precautionary approach should be adopted, with avoidance or minimization of allogeneic transfusion and the use of appropriate patient blood conservation techniques whenever possible.⁹

BASIC IMMUNOHEMATOLOGY

RBC serology is a specialized area of knowledge, and it is not possible to expect clinicians to have more than a basic working knowledge essential for patient safety.

Regular and Irregular (Atypical) Antibodies

The regular alloantibodies (isoagglutinins) of the ABO system are naturally occurring agglutinins present in all ABO types (except AB), depending on the ABO group. Group O people have anti-A and anti-B isoagglutinins, group A people have anti-B, and group B people have anti-A. Group A cells cause the most common and most dangerous ABO-incompatible hemolytic reactions.

Atypical antibodies are not normally present in the plasma but may be found in some people as naturally occurring antibodies or immune antibodies. Immune antibodies result from previous exposure due to blood transfusion or pregnancy. Naturally occurring antibodies are generally of minimal clinical significance. In contrast, many of the immune atypical antibodies are of major clinical significance, and their recognition is the *raison d'être* for pretransfusion compatibility testing and antenatal antibody screening. Blood group antigens vary widely in frequency and immunogenicity. The D antigen of the Rhesus (Rh) blood group system is common and highly immunogenic. When an Rh-negative (i.e., D-negative) patient is exposed to D-positive blood, there is a high likelihood of forming an anti-D antibody. For this reason, the D antigen is taken into account when providing blood for transfusion, in contrast to the numerous other RBC antigens that are less common or less immunogenic. Beyond the Rh(D), and sometimes the Kell (K) blood group antigens, it is not practical or necessary to take notice of other blood group antigens unless an atypical antibody is detected during antibody screening procedures.

Antibody Screen

On receipt of a blood sample by the transfusion service, the RBCs are ABO and Rh(D) typed, and the serum is screened for atypical antibodies. This screen consists of testing the patient's serum with group O screening cells. The screening panel consists of RBCs obtained from two group O donors containing all common RBC antigens occurring with a frequency of greater than approximately 2% in the community. If an atypical antibody is detected on the antibody screen, further serologic investigations are done to identify the specificity of the antibody. These investigations are time consuming and when possible should be carried out electively.

Crossmatch (Compatibility Test)

The crossmatch is the final compatibility test between the donor cells and the patient's serum. The crossmatch test tends to be overemphasized to the detriment of the antibody screen. With sophisticated knowledge of serology, the emphasis in the supply of compatible blood is now concentrated on the steps before the final compatibility crossmatch.

As precompatibility testing has assumed the major role in the selection of blood for transfusion, there has been a rethinking of policies relating to the supply of blood for elective transfusions. Whenever elective surgery is planned for a patient who is likely to require blood transfusion, the transfusion service must receive a clotted blood sample well before the anticipated time of surgery. Precompatibility testing should be carried out during routine working hours when facilities are geared for large workloads and enough staff are available to handle all contingencies. With computerization, electronic crossmatching is increasingly accepted as the standard for releasing compatible blood for patients with negative antibody screens.

When urgent clinical and laboratory decisions are made under conditions of stress, it is frequently difficult for all involved personnel to appreciate the difficulties of others. The decision to give uncrossmatched or partially crossmatched blood or to wait for crossmatch-compatible blood is not easy, and certain basic serologic considerations may clarify for the clinician some of the problems faced by the serologist. Depending on the degree of urgency and extent of previous knowledge about the patient's RBC serology, blood can be provided with varying degrees of safety. When a patient is exsanguinating and likely to die, however, giving ABO-compatible, uncrossmatched blood, especially if the antibody screen is negative, is safe and appropriate therapy.

Group O Rh(D)-negative donors are referred to as "universal" blood donors and are ABO compatible with all recipients. The blood is also screened for high-titer A or B hemolysins. The transfusions should be given as RBC concentrates and used only in emergencies. Group O Rh(D)-positive blood can be used in exsanguinating patients, but if the recipient is of childbearing age, every attempt should be made to give Rh(D)-negative blood until the patient's blood group is known.

Transfusion of blood of the correct ABO type circumvents the isoagglutinin problems alluded to earlier. Simple as this approach may seem, its safety depends on meticulous attention to grouping. Previous blood group information such as a "bracelet" group or "unofficial" group written in the patient's records may be incorrect, and there may be considerable risk if blood is administered on the basis of this information alone.

KEY POINTS

1. An evidence-based approach to blood component transfusion has resulted in many long-standing transfusion dogmas assuming clinical efficacy of the labile allogeneic blood components (red cells, platelets, and fresh frozen plasma) in improving clinical outcomes.
2. The decision to transfuse red blood cell concentrates should be supported by the need to relieve clinical signs and symptoms of impaired oxygen transport and to prevent morbidity and mortality, with the aim of improving clinical outcomes.
3. Allogeneic blood transfusion may be an independent risk factor for adverse clinical outcomes.
4. The development of clinical practice guidelines for the use of blood components should focus on patient blood management, and transfusion of allogeneic blood should no longer be the default decision in the context of clinical uncertainty.
5. The classic symptoms and signs of an acute hemolytic transfusion reaction include apprehension, flushing, pain (e.g., infusion site, headache, chest, lumbosacral, abdominal), nausea, vomiting, rigors, hypotension, and circulatory collapse.
6. A clinician needs a basic working knowledge of red blood cell serology to ensure patient safety.

Venous thromboembolism (VTE) is a common complication of serious illness and is associated with considerable morbidity and mortality in hospitalized patients. It represents the third most common cause of vascular death, after myocardial infarction and stroke, and is the leading preventable cause of death in hospitalized patients.^{1,2} Within the United States, there are approximately 600,000 to 900,000 cases annually with an overall mortality rate ranging between 15% and 53%.³ Within the ICU, patients with VTE are more likely to have a longer duration of mechanical ventilation (9 vs. 6 days; $P = 0.02$), ICU stay (17.5 vs. 9 days; $P = 0.005$), and hospitalization (51 vs. 21 days; $P < 0.001$). These patients also have significantly higher in-hospital mortality (56% vs. 38%).⁴ Recognizing that ICU patients often have multiple risk factors for VTE, increased attention has been placed upon the identification of risk factors, development of clinical prediction scores, and preventative strategies.

RISK FACTORS FOR VENOUS THROMBOEMBOLISM IN MEDICAL-SURGICAL ICU PATIENTS

Medical-surgical ICU patients demonstrate a higher risk of VTE than patients managed on medical or surgical ward services.⁵ Established risk factors for VTE may be classified within three general categories: stasis, vascular injury, and hypercoagulable state. Several clinical risk factors have been identified that may contribute significantly to the development of VTE. These factors may exist prior to ICU admission (e.g., acute and chronic illness, recent surgery, or trauma) or may be acquired during the admission (e.g., use of sedatives/paralytics and thrombin-generating invasive procedures). Observational studies in this patient population have identified several VTE risk factors to include female sex, previous VTE events, central venous catheterization, and comorbid conditions (e.g., malignancy).^{6,7} More recent prospective studies have further described these risk factors. In a prospective cohort study of 261 medical-surgical ICU patients, four independent risk factors were identified for ICU-acquired VTE: personal or family history of VTE (HR 3.9; 95% CI, 1.5-10), end-stage renal disease (HR 3.7; CI, 1.3-11.2), platelet transfusion (HR 3.2; 95% CI, 1.2-8.5), and vasopressor administration (HR 2.8; 95% CI, 1.1-7.2).⁴ These studies assist in characterizing VTE as a multifactorial disease process with both fixed and modifiable risk factors. Understanding these risk factors can aid in the development of effective preventative strategies as well as inform the role of screening and surveillance in this patient population.

PREVALENCE AND INCIDENCE

The prevalence and incidence of VTE in medical-surgical ICUs vary greatly among patient populations and are influenced by whether these events were clinically diagnosed or detected by screening methods. The prevalence of VTE at the time of admission in medical and surgical ICUs ranges from 7.5% to 10.7% in cross-sectional studies that have employed systemic screening methods.^{9,10} Based upon data from earlier longitudinal studies that utilized systematic screening with either lower extremity Doppler ultrasound or radioactive iodine fibrinogen scanning, the incidence of developing VTE (specifically DVT) during ICU

admission has ranged between 8.8% and 40%. More recent studies have identified a lower incidence of VTE events, suggesting a range between 9.8% and 26.6%.^{6,11,12} These findings may be due in part to changes in thromboprophylaxis practice.^{8,13,14} Both prevalence and incidence rates may be considerably higher in neurosurgical, trauma, and acute spinal cord injury patients.^{15,16}

PREVENTION

Patients admitted to medical-surgical ICUs are considered higher risk for VTE and should be evaluated thoroughly for early thromboprophylaxis within the first 24 hours of admission. In a retrospective observational study of 175,665 critically ill patients, ICU and in-hospital mortality were both significantly lower in those receiving thromboprophylaxis within 24 hours of admission than in those who did not (6.3% and 10.6% vs. 7.6% and 11.2%, respectively). The attributable mortality effect of omitting early thromboprophylaxis was 3.9% (95% CI, 2.2-5.6), 8.0% (95% CI, 5.6-10.4), 9.4% (95% CI, 6.4-12.4), and 15.4% (95% CI, 11.1-19.9) for patients with multiple trauma, sepsis, metastatic disease, and cardiac arrest, respectively.¹⁷ While no formally, prospectively validated risk assessment models exist, several empirically generated or data-derived risk models have been developed, to include the Padua Prediction Score, IMPROVE risk score, and GENEVA risk score (Tables 138-1, 138-2, and 138-3). For critically ill patients at moderate to high risk of VTE and low risk for bleeding, thromboprophylaxis with subcutaneous low-molecular-weight heparin (LMWH) or subcutaneous low dose unfractionated heparin (UFH) is recommended. For critically ill patients who are either bleeding or at high risk for major bleeding, mechanical thromboprophylaxis with graduated compression stockings (GCS) or intermittent pneumatic compression (IPC) devices are recommended until the bleeding risk decreases, at which time transition to pharmacologic thromboprophylaxis may be substituted.¹⁸ Although it is common practice to insert inferior vena cava (IVC) filters in high-risk trauma patients who may also have a high risk of bleeding, there are no high-quality data to support this practice. A meta-analysis of controlled observational studies suggests a reduction in PE and fatal PE with no effect on the rates of DVT.¹⁹ Table 138-4 outlines a generalized approach to VTE prevention in medical-surgical ICUs.

DIAGNOSIS

Clinical Evaluation and Prediction

Clinical evaluation, including risk factor consideration, physical examination, laboratory/imaging studies, and cardiovascular monitoring, are integral to the assessment of a patient's risk for early mortality and to providing optimal management.^{20,21} However, evaluation for VTE can be challenging within the ICU. Often, patients may be mechanically ventilated or demonstrate altered mentation that does not allow for the timely identification of symptoms. Many patients may also have comorbid conditions that confound or complicate the diagnostic process.

Classification of patients into pretest probability categories corresponding to their likelihood of VTE, whether assessed by clinical judgment or by a validated prediction rule, allows the selection of the

most appropriate diagnostic pathway. Several clinical prediction rules have been developed to assist in the objective evaluation of pretest probability for VTE. Of the existing prediction rules, the Wells score is one of the most extensively validated and most commonly used score to identify patients according to their probability of VTE²²⁻²⁵ (Table 138-5). Despite extensive validation and widespread use, the Wells score has not been evaluated in critically ill patients, and its role in the diagnosis of VTE remains unclear within this patient population.

Data from Wells PS, Anderson DR, Rodger M, et al. Derivation of a simple clinical model to categorize patients probability of pulmonary embolism: increasing the models utility with the SimpliRED D-dimer. *Thromb Haemost* 2000;83:416-420.

Diagnostic Testing

Several laboratory and imaging modalities have been suggested to assist in the diagnosis of VTE. D-dimer is a fibrin degradation product present during clot degeneration and is a marker of thrombotic disease. Enzyme-linked immunosorbent assays (ELISA) are widely used to quantify plasma D-dimer concentration in patients and demonstrate favorable performance characteristics for excluding VTE in patients with low to moderate probability of pulmonary embolism (sensitivity 0.95; 95% CI, 0.85-1.0).²⁶ However, most patients in the ICU setting would be less likely to be classified as low probability, which considerably limits its clinical utility. Additionally, there is evidence to suggest that the specificity in hospitalized patients may be lower. In a prospective study of 239 medical ICU patients, D-dimer was negative in only 16% of patients, and three of these patients were subsequently diagnosed with VTE.²⁷ Given these limitations, D-dimer should be used with caution in the ICU, and patients with a high pretest probability for VTE should be evaluated by an alternative diagnostic modality.

Computed tomography pulmonary angiography (CTPA) has become the primary diagnostic test for pulmonary embolism (PE). It may also provide additional information such as the assessment of the right ventricular (RV)/left ventricular ratio to identify RV overload, enabling estimation of the severity of PE in addition to a positive diagnosis.²⁸ Based upon data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) II study, in patients with a moderate or high clinical probability of PE, the positive predictive values of CTPA were 92% and 96%, respectively.²⁹ However, CTPA does have diagnostic limitations and may not be able to reliably exclude PE when the clinical probability is high. In patients with a high pretest probability of PE, the negative predictive value is only 60% and further

evaluation may be required.²⁹ When evaluated specifically in ICU and trauma populations, CTPA demonstrated similar performance characteristics.^{30,31}

The results of the Prospective Investigation Study of Acute Pulmonary Embolism Diagnosis (PISA-PED) suggest that perfusion scanning, combined with clinical assessment, may reduce the need for angiography and provide a viable diagnostic alternative.³² This technique may be appealing in certain patient populations, such as renal insufficiency or pregnancy, and may circumvent limitations (e.g., contrast agents, ionizing radiation exposure) associated with CTPA.³³ Based upon data from the PIOPED II study, in patients with a high clinical suspicion for PE and high-probability V/Q scan, the clinical probability of PE was 96%. However, in patients with a high clinical suspicion for PE and low-probability V/Q scan, the clinical probability of PE was still 40%. In patients with all other combinations of clinical suspicion and scan results, the probability of PE ranged from 6% to 88%.³⁴ In these situations, clinical judgment must be used, and additional diagnostic modalities should be considered. To limit the possibility of nondiagnostic results, V/Q scans should ideally be used in patients with a normal chest radiograph. However, patients with concurrent cardiopulmonary processes are common in ICU populations (e.g., pneumonia, atelectasis, pulmonary edema, pleural effusion), thereby potentially limiting its diagnostic utility in some patients. Additionally, transport and image acquisition time are higher for V/Q, thus making it a less attractive option for unstable ICU patients.

As approximately 50% to 70% of patients with confirmed PE have a proximal DVT, lower extremity Doppler ultrasound may be a useful adjunctive diagnostic study.^{20,35,36} In patients with symptomatic proximal DVT, meta-analysis suggests a pooled sensitivity of 97% (95% CI, 96-98). In asymptomatic patients, a pooled sensitivity of 62% (95% CI, 53-71) was reported.³⁷ Unfortunately, many critically ill patients may be sedated and unable to report typical symptoms or may have bilateral lower extremity swelling, thus potentially reducing the sensitivity in this population. Two-point complete compression ultrasonography (CCUS) has been proposed as an alternative technique for rapid and/or serial bedside assessment of DVT. In a prospective study of 2098 patients with symptomatic DVT, similar diagnostic accuracy was observed in patients undergoing whole leg Doppler ultrasonography and CCUS.³⁸ CCUS may also provide useful prognostic information that may assist in risk stratification. In a prospective cohort of patients diagnosed with acute symptomatic PE who subsequently underwent CCUS screening, patients with concomitant DVT had an increased all-cause mortality (HR 2.05; 95% CI, 1.24-3.38, $P = 0.005$) and PE-specific mortality (HR 4.25; 95% CI, 1.61-11.25; $P = 0.04$) compared with those without DVT.³⁶

Transthoracic echocardiography (TTE) can be a useful adjunct in the diagnosis and management of VTE; however, as the reported sensitivity of TTE for the diagnosis of PE is approximately 60% to 70%, a negative result cannot reliably exclude PE.²⁰ Nevertheless, in patients with suspected PE presenting with shock or hypotension, the absence of echocardiographic signs of RV overload or dysfunction practically excludes PE as a cause of hemodynamic instability.²⁰ In addition, echocardiography can identify the presence of a concurrent RV thrombus, which is a marker of worse prognosis (14-day mortality: 21% vs. 11%; 3-month mortality: 29% vs. 16%), as well as provide insight into RV function and pulmonary artery pressures.³⁹ As such, TTE may be a useful adjunctive diagnostic modality to assist in the confirmation/exclusion of PE as well as provide useful diagnostic information for risk stratification.

RISK STRATIFICATION

In patients with confirmed PE, initial risk stratification is based upon clinical assessment of hemodynamic status.^{18,20} Assessment of hemodynamic status is used to guide diagnostic and treatment decisions.

High-risk (or massive) PE results in hemodynamic instability and represents a life-threatening emergency, which may be associated with an in-hospital mortality rate in excess of 50%.³ The American College

of Chest Physicians (ACCP) define hemodynamically unstable PE as PE associated with shock or hypotension (systolic blood pressure <90 mm Hg) or systolic pressure drops of ≥ 40 mm Hg for >15 minutes if not caused by new-onset arrhythmia, hypovolemia, or sepsis.^{18,20} The ACCP definition also includes patients at risk of developing hypotension.¹⁸

In hemodynamically stable patients, the purpose of further risk stratification is to differentiate those patients who are normotensive and have a low risk of all-cause mortality (low-risk or nonmassive PE) from those patients with preserved systemic arterial pressure who possess increased risk of PE-related adverse clinical events (intermediate-risk or submassive PE). Prognostic models, laboratory testing, and imaging studies may assist with classification of patients into these categories.²⁰

Identification of patients with PE who have a low risk of complications associated with PE and its therapy may assist in determining the appropriate disposition of patients to ICU or medical-surgical ward services. Risk stratification models can accurately identify patients at low risk of death within the first 3 months after the diagnosis of PE. Two clinical models commonly used for estimating prognosis in patients with PE are the Pulmonary Embolism Severity Index (PESI) and the Geneva Score, which have both been extensively validated, and may assist in the risk stratification of these patients⁴⁰⁻⁴³ (Table 138-6 and 138-7).

Identification of patients at high risk for complications associated with PE can assist in the selection of patients for escalation of PE therapy (e.g., transfer to the intensive care unit for observation and/or consideration of thrombolysis). RV dysfunction, induced by the increased load caused by pulmonary obstruction and the release of vasoconstrictive substances in response to reduced blood flow in the pulmonary vasculature, is associated with a poor prognosis.^{18,20,44} Myocardial injury is also associated with short-term mortality and adverse outcomes in patients with acute PE.²⁰ Markers of RV dysfunction (via echocardiography, spiral computed tomography, or brain

natriuretic peptide testing) and myocardial injury (via cardiac troponin T or I) are able to assist in the identification of intermediate-risk patients with PE.^{20,45,46} At present, no single test is sufficient to provide a positive predictive value for PE-specific mortality to guide the initiation of escalation of therapy. However, recent studies have suggested that evaluation utilizing combined diagnostic testing may provide useful prognostic information. In a prospective study of 591 normotensive patients with PE, evaluation using a two-test strategy, cardiac troponins/TTE or cardiac troponins/CCUS, in high-risk patients (per PESI risk stratification) demonstrated a positive predictive value for 30-day PE-related mortality of 20.7% and 24.4%, respectively.⁴⁷ Therefore, a combined diagnostic testing strategy may be helpful in further risk stratifying patients within this intermediate-risk group and improve prognostication. Recently, a simple four-factor prediction score for the identification of normotensive patients with acute PE at high risk of adverse PE-related clinical events (intermediate risk) has been developed and validated^{48,49} (Table 138-8).

TREATMENT

Treatment of VTE is guided by risk stratification, and first-line therapy varies depending on hemodynamic status.

Low-Risk Hemodynamically Stable PE

For low-risk hemodynamically stable patients, parenteral anticoagulation with subcutaneous LMWH, subcutaneous or intravenous UHF, or subcutaneous fondaparinux followed by bridging therapy to a vitamin K antagonist (VKA) is the cornerstone of standard treatment. VKA therapy may begin on the first or second day of heparin therapy and should overlap for a minimum of 5 days.^{18,20} More recently, several direct oral anticoagulants (rivaroxaban, apixaban, edoxaban, and dabigatran) have been approved for the treatment of hemodynamically stable VTE and provide an alternative treatment option in selected patients.⁵⁰⁻⁵²

Intermediate-Risk Hemodynamically Stable PE

Standard treatment of intermediate-risk PE is similar to patients with low-risk PE. However, the consideration of escalation of therapy in a selected subgroup of patients at higher risk for complications associated with PE remains controversial. While there is evidence that thrombolytic therapy in selected intermediate-risk patients with PE may result in both an acute and long-term improvement in pulmonary artery pressures as well as RV function, there has been no definitive evidence of mortality benefit in this patient population.⁵³ In the Pulmonary Embolism Thrombolysis Study (PEITHO), intermediate-risk normotensive patients with evidence of RV dysfunction on TTE or CTPA as well as myocardial injury indicated by positive cardiac troponins demonstrated improvements in the primary composite outcome

(death from any cause or hemodynamic collapse within 7 days) when treated with heparin/tenecteplase versus heparin/placebo (2.6% vs. 5.6%; OR 0.44; 95% CI, 0.23-0.87; $P = 0.02$). However, there was no statistically significant difference in the rate of all-cause mortality between the groups at 7 days (1.2 vs. 1.8%, $P = 0.42$) and 30 days (2.4% vs. 3.2%, $P = 0.42$). Additionally, the tenecteplase group demonstrated increased rates of both stroke (2.4% vs. 0.2%, $P = 0.03$) and extracranial bleeding (6.3% vs. 1.2%, $P < 0.001$).⁵⁴ While a recent meta-analysis suggests a potential mortality benefit in intermediate-risk patients, particularly those less than 65 years of age, the analysis was heavily influenced by the PEITHO trial, in which the primary outcome was driven primarily by clinical deterioration and rescue thrombolysis.⁵⁵ This suggests that a more reasonable approach may be close monitoring of these patients, reserving reperfusion therapy for those who demonstrate clinical deterioration.

High-Risk Hemodynamically Unstable PE

In patients with hemodynamically unstable PE, in which restoration of pulmonary arterial flow is urgently required due to the risk of RV failure, thrombolytic therapy with intravenous streptokinase, urokinase, or recombinant tissue plasminogen activator (tPA) is suggested and is associated with a significant reduction in the composite outcome of recurrent PE or death compared with heparin monotherapy.^{18,20,56} In a prospective single-center registry of patient with acute PE who underwent thrombolytic therapy, 91.8% of patients demonstrated improvement in hemodynamic stability and RV dysfunction.⁵⁷ However, the use of thrombolytic agents in acute PE has been associated with a greater overall rate of major bleeding (9.2% vs. 3.4%; OR 2.73; 95% CI, 1.91-3.91) and intracranial hemorrhage (1.5% vs. 0.2%; OR 4.63; 95% CI, 1.78-12.04).⁵⁵ Short infusion times (2 hours) are preferred over prolonged infusions (24 hours) as shorter infusion times are associated with more rapid clot lysis and a reduced risk of bleeding.¹⁸ Upon completion of thrombolytic infusion, full anticoagulation with heparin is typically performed prior to transition to a VKA.

In patients with hemodynamically unstable PE in whom thrombolytics are contraindicated or have failed or in those experiencing shock that is likely to cause death before systemic thrombolysis can take place, catheter-assisted thrombus removal may be considered.^{18,20} Several techniques have been proposed, to include rheolytic thrombectomy, aspiration thrombectomy, ultrasound-accelerated thrombolysis, and catheter-directed tPA. While several of these techniques show promise, there is insufficient evidence to support any one individual technique at this time.

In patients with hemodynamically unstable PE who have failed both systemic and catheter-directed thrombolysis or are experiencing shock that is likely to cause death before thrombolysis can take effect, surgical pulmonary embolectomy should be considered, although the evidence supporting these recommendations is limited.^{18,20} In a recently

published retrospective review of twenty patients with acute PE and RV dysfunction who had contraindications to thrombolysis, 95% of patients undergoing pulmonary embolectomy survived to hospital discharge.⁵⁸ Surgical pulmonary embolectomy may be a viable option for a selected patient population with contraindications to thrombolysis or profound clinical instability.

Indications for IVC filters for the treatment of acute PE are currently the same as in other populations. Evidence-based guidelines recommend their use in patients who cannot receive anticoagulant therapy, those who develop significant bleeding while on anticoagulation, and those who develop recurrent thrombosis on therapeutic anticoagulation.¹⁸

KEY POINTS

1. VTE is a common complication of serious illness, and medical-surgical ICU patients are likely to have multiple fixed and modifiable VTE risk factors.
2. Implementation of thromboprophylaxis in appropriately selected patients is vital to reduce the incidence of VTE and its associated complications including death, prolonged ventilation, and prolonged hospital and ICU stay.
3. Clinical prediction scores in conjunction with diagnostic testing (e.g., CTPA, V/Q, CCUS, TTE) can assist in the timely and accurate diagnosis of patients with suspected VTE.
4. Risk stratification based upon hemodynamic stability and risk for VTE-associated complications is used to determine treatment strategies.
5. High-risk hemodynamically unstable patients should be considered for immediate systemic and/or catheter-directed thrombolytic therapy. The role for escalation of therapy in intermediate-risk hemodynamically stable patients with significant risk for VTE-associated complications remains unclear.

OVERVIEW OF EFFECTIVE COAGULATION

The classic cascade model of coagulation, although still widely taught and utilized, is out of date. According to this model, coagulation can be initiated by the activation of either the “extrinsic” or “intrinsic” pathway, which converge on factor X and generate thrombin with the subsequent formation of fibrin. This outdated model fails to explain many clinical scenarios, and the current understanding of the biochemistry of hemostasis is far more nuanced and complex. The cell-based model of coagulation emphasizes the important roles of tissue factor (TF)-bearing cells and platelets in hemostasis.¹⁻² This model regards thrombus formation as the result of overlapping processes: initiation, amplification, and propagation.²

Initiation occurs on the surface of a TF-expressing cell (typically fibroblasts, immunostimulated endothelium cells, and monocytes). This interaction of TF with plasma leads to the TF-FVIIa complex, which in turn, promotes localized FXa, FIXa, and thrombin generation that can serve to activate platelets. The localization of activated platelets at the site of injury allows for diffusion of FIXa to activate the intrinsic pathway, creating a much larger burst of thrombin (*amplification*). The platelet surface is well suited for the task of bringing together von Willebrand factor (vWF), coagulation factors, and fibrinogen. This activated surface allows further *propagation* to occur with continued activation of the intrinsic pathway of coagulation.²

The complex interplay of the vascular endothelium, coagulation enzymes, vWF, and platelets cannot be evaluated by any current laboratory analysis. Further, disease processes have their own unique pattern of disturbances of the hemostatic system.¹⁻⁶

BASIC CONDITIONS NECESSARY FOR PROPER HEMOSTASIS

Bleeding can be the primary reason for admission or a secondary insult while in the intensive care unit (ICU). Although coagulopathy may be the driver of or an important contributor to bleeding, an anatomic source of bleeding may require imaging studies, endoscopy, or surgical exploration as the most important initial evaluation.

Ionized calcium is a necessary cofactor in the coagulation cascade. Citrate anion is capable of binding (chelating) ionized calcium, and this is how the citrate component of ACD (acid citrate dextrose) buffer leads to anticoagulation. Massive resuscitation of patients with citrated blood products can lead to hypocalcemia. Repletion of calcium should be part of the resuscitation when patients require massive transfusion.⁷

Hypothermia may be a deliberate therapeutic maneuver or an accidental occurrence associated with surgery, trauma, or exposure. Body temperatures less than 33°C lead to slowing of the enzymatic reactions in the coagulation cascade.⁶ Platelet activation is maintained at temperatures down to 33°C, but at higher temperatures, conformational changes occur in platelets that decrease their adhesion.^{6,8} The localization of platelets to the site of injury is necessary for amplification and propagation of coagulation, and decreased adhesion may contribute to clinical bleeding observed between 33°C and 37°C.⁶

Acidosis has an equally important effect on the coagulation system. The optimal pH for proteolytic activity of coagulation enzymes is well above physiologic pH.⁹ A blood pH of 7.2 decreases the activity of the

FXa/FVa complex by 50%.⁹ Fibrinogen degradation increases in an acidemic environment, and fibrinogen levels drop.¹⁰ The coagulopathy associated with acidemia is not corrected with infusion of bicarbonate.¹¹ Ensuring the appropriate environment for proper function of coagulation factors and platelets is as important as correcting detectable coagulopathy.

LABORATORY ANALYSIS OF COAGULATION

Traditional Measures of Coagulation

Traditional measures of coagulation include the prothrombin time (PT), activated partial thromboplastin time (aPTT), fibrinogen level, and platelet count. These are the most widely available and utilized tests and will be discussed first.

Both the PT and aPTT are measures taken from the acellular plasma component of a citrated blood sample that has been centrifuged. PT uses thromboplastins to activate FVII and the extrinsic pathway.¹² Most laboratories will report an international normalized ratio (INR) based on a correction in relation to the International Reference Preparation. PT will be prolonged in the setting of deficient or inactive factors VII, X, V, and II. The aPTT uses partial thromboplastins to activate the intrinsic pathway.¹² The aPTT will be prolonged in settings of deficient or inactive factor XII, XI, IX, VIII, X, and II; high molecular weight kininogen; and/or kallikrein. These tests are helpful for identifying factor insufficiencies or the presence of circulating inhibitors but cannot assess the overall risk of hemorrhage.¹³ Additionally, in patients who have suffered large volume hemorrhage with clinical coagulopathy, different commercially available tests variably identify dilutional coagulopathy.¹⁴

Fibrinogen level can be measured with quantitative immunochemical methods. Most laboratories, however, report a fibrinogen level that is derived from a functional analysis of fibrinogen activity. The most basic assessment of fibrinogen activity is the thrombin time (TT). For this assay, thrombin is added to plasma and the time to stable clot formation is recorded. Quantitative analysis of fibrinogen modifies the TT by diluting the patient's plasma and adding higher levels of thrombin. The time to clot formation is correlated to a standard dilution chart and converted to a concentration. Using this assay, the reporting of a low fibrinogen concentration can reflect true hypofibrinogenemia or the presence of a dysfunctional form of the protein. Fibrinogen is vital for the formation of a stable thrombus, and unlike PT/aPTT, fibrinogen levels have been shown to be predictive of procedural bleeding.¹⁵⁻¹⁷

Platelet count does not provide a functional assessment of platelets, but thrombocytopenia can exacerbate bleeding; very low platelet levels are associated with spontaneous hemorrhage. Significant spontaneous bleeding with intact endothelium is unlikely to occur unless the platelet count is less than 5000/ μ L.¹⁸ Randomized trials comparing prophylactic transfusion triggers of 10,000/ μ L to 20,000/ μ L showed no difference in bleeding.¹⁸ Suggested trigger levels are 50,000 for patients having procedures or with active bleeding and 100,000 for neurologic surgical procedures, though these are consensus levels without supportive data.¹⁸ Although a low platelet count is helpful in evaluating the bleeding patient, a normal platelet count does not preclude platelet dysfunction.

Measures of Platelet Function

Many bleeding patients have a normal platelet count but might have platelet dysfunction caused by uremia, cardiopulmonary bypass, or other predisposing factors. Other bleeding patients have a platelet count that is only slightly less than normal, and the decision whether to transfuse platelets is unclear. Fortunately for clinicians, numerous laboratory tests measure platelet function. The most commonly used tests rely on a platelet agonist (e.g., adenosine diphosphate [ADP], epinephrine, ristocetin, thrombin receptor agonist peptide [TRAP]), exposure to shear stress, or both to activate platelets. These tests monitor the rate of platelet aggregation through changes in light transmission, light scattering, electrical impedance, platelet aggregation on a plate, or occlusion of a tube.^{19,20}

The platelet function analyzer (PFA-100, Dade Behring, Miami, FL) utilizes citrated whole blood exposed to high shear stress within a capillary tube coated with collagen and either ADP or epinephrine. It subsequently monitors flow rate and reports a closure time.²¹ The test is sensitive to vWF deficiency and can be used to monitor for deficiency or response to desmopressin.¹⁹ The test is sensitive to both thrombocytopenia (platelet count < 100,000/ μ L) and anemia (hematocrit < 30%), so results should be interpreted with a complete blood count.^{21,22} Since both anemia and thrombocytopenia are common in ICU patients, the usefulness of this method in the context of critical illness is limited.

The Multiplate Analyzer (Verum Diagnostica, Munich, Germany) exposes platelets in multiple channels to platelet activators, and aggregation is monitored through changes in electrical impedance.²³ This test is extensively used to monitor the effect of platelet antagonism with aspirin and P2Y₁₂ antagonists (e.g., clopidogrel, prasugrel) with the ASPI test and ADP test, respectively. TRAP acts as the most active stimulator of platelets and is used as a control in antiplatelet monitoring. For intensivists, decreased response to TRAP is an excellent test for overall platelet function. The Multiplate system has been evaluated in both cardiac surgery and trauma.²³⁻²⁵ Unlike the whole blood clotting assays that will be discussed next, the benefit of dedicated platelet function assays is their ability to reliably detect the effect of platelet antagonists.²⁰

Whole Viscoelastic Hemostatic Assays

With further elucidation of the cell-based model of hemostasis, the desire has arisen for testing approaches that evaluate the interplay of the enzymatic and cellular components of coagulation. The following tests assess the interaction of coagulation factors and platelets: rotational thromboelastography (ROTEM; ROTEMVR) (TEM International, Munich, Germany) and thromboelastography (TEG; TEGVR) (Haemonetics, Braintree, MA, USA).

Both TEG and ROTEM are viscoelastic tests of hemostasis in whole blood that measure time to clot formation, strength, and dissolution kinetics.²⁷ TEG relies on a rotating cup of whole blood with a pin on a torsion wire suspended in the cup. As a clot forms, the rotation of the cup is transmitted to the wire. In the ROTEM assay, the cylindrical cup containing blood is held steady while a suspended pin in the sample oscillates at a constant force.²⁷ Although a minor change, the ROTEM system is less sensitive to external motion, which enhances its ability to be used in a point-of-care setting.

Newer TEG and ROTEM systems differ from traditional TEG in their utilization of activators to accelerate the process for timely acquisition of data. Both assays provide similar data on clot formation and kinetics, but the values are not interchangeable because of differences in the methods. As they are trademarked enterprises, the nomenclature differs. The initial time to clot formation (CT in ROTEM and R for TEG) is the time it takes for the tracing to reach 2 mm. The clot formation time (CFT) in ROTEM and the kinetics time (K) in TEG are measured as the time for the tracing to increase from 2 mm to 20 mm. The angle is created from the developing curve from the point of clot initiation. Maximal clot firmness (MCF) in ROTEM and maximal

amplitude (MA) in TEG are the peak amplitudes and a measure of overall clot strength. Lysis at 30 and 60 minutes after MA is recorded in TEG, and the Lysis Index 30 is the percent reduction from MCF 30 minutes after CT in ROTEM.²⁷

The TEG system has two channels and ROTEM has four. The presence of multiple channels allows simultaneous evaluation of clot formation with multiple activators or inhibitors. The standard ROTEM analysis includes INTEM (activation with phospholipid and ellagic acid), EXTEM (activation with tissue factor), and FIBTEM (activation with cytochalasin D followed by tissue factor). Additional tests can include heparinase before ellagic acid (HEPTEM) and aprotinin followed by tissue factor (APTEM).

The CT of an INTEM assay provides data similar to an aPTT. The CT with the EXTEM assay provides data similar to a PT/INR. HEPTEM gives the data of the INTEM without the effect of circulating heparin. These data points are available within minutes and help guide therapy with fresh frozen plasma, prothrombin complex concentrates, vitamin K, or activated factor VII.

The CFT, alpha angle, and MCF are all sensitive to deficiencies in platelet or fibrinogen activity (due to dilution or dysfunction). Further differentiation of platelet and fibrinogen contributions to dysfunction can be obtained by including the FIBTEM analysis. The addition of cytochalasin D inhibits platelets, thus assessing the component of clot strength from fibrin alone. A FIBTEM MCF >12 largely precludes clinically important bleeding secondary to fibrinogen dysfunction or dilution. Measures of lysis take longer to obtain but can alert the clinician to coagulopathy from fibrinolysis.

A Cochrane review in 2011 determined that both TEG- and ROTEM-guided algorithms reduced bleeding without other significant improvements in patient outcome.²⁸ Further trials showing improvements in bleeding, transfusion, and patient-centered outcomes have come out since that review.²⁹ Further data and experience with TEG and ROTEM will likely lead to greater availability and exposure to these tests.

Disseminated Intravascular Coagulation (DIC) Scores

DIC is a syndrome resulting from diffuse hemostatic activation leading to small vessel thrombosis and, eventually, consumptive coagulopathy.³⁰ As activation of the hemostatic system and abnormal lab values are present in almost all critically ill patients, simple scoring systems for identifying patients with DIC have been created and validated.³¹ The International Society of Thrombosis and Haemostasis DIC scoring system uses points assigned as follows for routine lab results in patients with disease states associated with DIC: platelet count (>100,000/ μ L, 0; <100,000/ μ L, 1; <50,000/ μ L, 2); fibrin-related markers (no increase, 0; moderate increase, 1; strong increase, 2), PT (<3 sec, 0; >3 sec but <6 sec, 1; >6 secs, 2); fibrinogen level (>1.0 g/L, 0; <1.0 g/L, 1).³¹ A score of 5 or greater has a sensitivity of 93% and specificity of 98% for diagnosing DIC.³¹ Although current management of DIC is supportive and directed at the underlying disease process, having a simple diagnostic tool allows for accurate risk stratification.

Monitoring Anticoagulation

Unfractionated Heparin (UFH), Low Molecular Weight Heparin (LMWH), and Fondaparinux

UFH, LMWH, and fondaparinux all require the activation of antithrombin for their anticoagulant effect. UFH and LMWH are mixtures of negatively charged glycosaminoglycans, whereas fondaparinux is a synthetic polysaccharide.³² UFH can be reliably monitored with the aPTT until higher plasma concentrations are achieved, at which point an activated clotting time (ACT) test is necessary to accurately assess anticoagulation. Protamine titration assays are available with ACT systems, allowing accurate assessment of residual heparin effects. PT is typically not affected by heparin at low concentrations because

polybrene, a heparin neutralizing substance, is used in most commercial thromboplastins. LMWH and fondaparinux do not uniformly affect the aPTT, and anti-Xa assays calibrated to the particular agent are necessary for monitoring.³²

Vitamin K Analogs (VKA)

The most commonly used VKA is coumadin. The degree of anticoagulation is reliably measured with the international normalized ratio (INR) of the PT.

Non-vitamin K Oral Anticoagulants (NOAC): Dabigatran, Apixaban, Rivaroxaban

Dabigatran is a direct inhibitor of free and clot-bound thrombin. It can prolong both the aPTT and PT. Unfortunately, the effect on different commercial assays varies widely.³² The thrombin time (TT) is exquisitely sensitive to low concentrations of dabigatran and can be used to exclude residual activity.^{32,33} For quantification of drug levels, dilute TT and ecarin clotting times can be used.^{32,33}

Apixaban and rivaroxaban are direct Xa inhibitors.^{32,33} Although both can alter the PT and aPTT, this effect is not reliable, and normal values do not preclude clinically relevant drug concentrations.³³ Activity can be reliably measured with anti-Xa assays that are calibrated for the drug in question, and negative anti-Xa assays preclude clinically relevant concentrations.³³

Direct Thrombin Inhibitors: Argatroban, Bivalirudin

Direct thrombin inhibitors reliably prolong both the aPTT, PT, INR, and ACT. For therapeutic monitoring, the aPTT or ACT can be used.³⁴ As argatroban prolongs the INR, it should be discontinued while transitioning to coumadin if the INR is greater than 4 with an aPTT within goal.³⁴

KEY POINTS

1. The classic cascade model of coagulation inadequately explains in vivo hemostasis. The cell-based model emphasizes the role of tissue-factor-bearing cells and platelets in initiation, amplification, and propagation.
2. Patient temperature, pH, and serum calcium should be monitored in the bleeding patient.
3. aPTT, PT, INR, platelet count, and fibrinogen assays are widely available and are standard in the workup of coagulation. The INR does not accurately predict bleeding. Platelet count cannot assess platelet function.
4. Platelet function assays are available for detecting platelet dysfunction due to disease or antiplatelet agents.
5. ROTEM and TEG allow for evaluation of whole blood clotting. These tests assess coagulation factor activity, platelet function, fibrinogen activity, and fibrinolysis.
6. DIC scores are determined using widely available lab tests and have good sensitivity and specificity.
7. Heparin, argatroban, and bivalirudin can be monitored with ACT and aPTT. Coumadin is monitored with INR. LMWH, fondaparinux, apixaban, and rivaroxaban can all be monitored using anti-Xa assays with normalized curves for the specific agent. Dabigatran activity can be ruled out with a normal TT.

Patients in an intensive care unit (ICU) often have received or require anticoagulation for multiple reasons that include acute thrombotic issues, mechanical valves, venous thromboembolic prophylaxis, atrial fibrillation, and ischemic cardiovascular disease. The types of anticoagulation and need for therapy vary depending on whether patients have arterial or venous thromboembolic issues. These issues are important in critically ill patients and have important perspectives for management. The concept of anticoagulation and the various therapeutic approaches have rapidly changed over recent years with the advent of many new anticoagulation agents that will be considered here.¹ In addition, there are important links between coagulation and other important physiologic responses including inflammation that are beyond the scope of this review.

ICU patients are anticoagulated for both thrombosis treatment and thromboprophylaxis. As initially mentioned, this includes a broad spectrum of potential indications. Although multiple therapeutic agents prevent or treat thrombosis in pathologic states, it is important to consider that all anticoagulation agents can cause bleeding. Thus, causes of bleeding in an ICU setting often are due to an acquired hemostatic defect due to alterations in the physiologic equilibrium of procoagulant and anticoagulation balances. Under normal physiologic states in healthy patients, anticoagulation is favored due to a multitude of mediators and vascular endothelial cells.¹ After vascular injury due to metabolic causes, surgery, or trauma, patients also develop procoagulant changes that alter this complex balance.¹ As a result, hemostasis and coagulation are far more complex than the simplified coagulation cascades that most clinicians have learned or considered.²⁻⁵ There is a complex equilibrium among blood cells, platelets, coagulation factors, natural inhibitors of coagulation, and the fibrinolytic system.⁶

In ICU settings, patients may receive anticoagulants for venous thromboembolism (VTE) that include deep vein thrombosis (DVT) and pulmonary embolism (PE) for either prevention or therapy.³ Patients may also have additional problems that include acute coronary syndromes, percutaneous coronary interventions (PCIs), or with an acute ischemic stroke that are arterial issues. Arterial thrombi are mediated by platelet responses, and important interactions exist in hemostasis and thrombus formation.^{4,7} With an arterial injury, injury or rupture of an atherosclerotic arterial plaque serves as a procoagulant focus for clot formation due to platelet adhesion, activation, and aggregation with the clinical end result of myocardial infarction or stroke.^{8,9} Platelets normally circulate in an inactivated state, but following activation as described, they express glycoprotein IIb/IIIa receptors that allow fibrinogen to bind, cross-link platelets, aggregate, and form a thrombus.⁹ Vascular injury causes thrombin formation but also platelet activation and the formation of the platelet-fibrinogen plug. Since platelets have a pivotal role in the pathogenesis of thrombosis after plaque rupture, antiplatelet agents including aspirin, thienopyridines (clopidogrel, prasugrel, ticagrelor), and the glycoprotein IIb/IIIa inhibitors reduce adverse events that are associated with plaque rupture.^{10,11,12}

Patients therefore commonly present in the ICU with underlying hemostatic disorders because of preexisting preoperative anticoagulation or antiplatelet therapy.¹³ All therapies that prevent clot from forming in pathologic states also interfere with normal hemostasis, an important mechanism to protect patients from exsanguination.^{14,15}

Multiple anticoagulation agents are administered in the ICU setting that include low-molecular-weight heparins (LMWHs), oral

anticoagulants (vitamin K antagonists (VKAs)/warfarin and the new target-specific oral agents apixaban, dabigatran, edoxaban, or rivaroxaban), platelet inhibitors (the thienopyridines clopidogrel, prasugrel, or ticagrelor), or direct thrombin inhibitors (r-hirudin, bivalirudin, argatroban).^{1,16-18} This review will focus on current pharmacologic anticoagulation therapies ICU patients may receive and the therapeutic perioperative and prohemostatic pharmacologic approaches that are used to treat or prevent bleeding in this setting.

■ ANTICOAGULATION

The basis of anticoagulation is modulating clot formation by inhibiting both thrombin activation and platelet activation.^{17,19-21} Thrombin is a critical component of hemostasis (stopping bleeding) and a critical procoagulant in coagulation. Thrombin catalyzes the formation of fibrin from soluble fibrinogen, but also activates factors V and VIII, and platelets.⁴ Activated platelets adhere to injured vascular endothelium through a von Willebrand factor bridge between the vasculature and the platelets. Platelets also, when activated, express IIb/IIIa receptors where fibrinogen binds, causing aggregation, but also facilitate the further generation of thrombin.²² There are also complex humoral amplification pathways that link both inflammatory and coagulation responses to generate thrombin and prothrombotic effects.^{14,23} Thus, anticoagulation is based on inhibiting thrombin activation, platelet activation, and/or both. Thrombin is a potent procoagulant that generates fibrin from soluble fibrinogen, activating factors V and VIII, and activating platelets. Activated platelets adhere to injured vascular endothelia, express IIb/IIIa receptors, aggregate, and further increase thrombin generation. Current and future anticoagulants used to prevent clot formation will be considered.

■ HEPARIN

Heparin, the most commonly used anticoagulant, especially in an ICU setting, is isolated from porcine intestine where it is stored in the mast cell granules. Unfractionated heparin (UFH) is a combination of 3000- to 30,000-Dalton (da) fragments.²⁴ Heparin binds to antithrombin III (also called antithrombin/AT), increasing the rate of thrombin-AT complex formation, but also inhibits other steps in coagulation.²⁴ Heparin anticoagulation has major advantages in an ICU setting as it can be rapidly reversed with protamine, has a short half-life of ~1 hour, and one of the few anticoagulants that can be readily administered in patients with renal dysfunction that may otherwise prolong the half-lives of most agents.²⁵ One of the major side effects of UFH is heparin-induced thrombocytopenia (HIT) that can occur in ~1% to 5% of ICU patients, especially postoperatively and following cardiac surgery with cardiopulmonary bypass.²⁶

Low-Molecular-Weight Heparins (LMWH)

Low-molecular-weight heparins (LMWHs) are purified from UFH, with an average molecular weight of ~5000 da.²⁰ LMWHs have a longer half-life, are only partially reversible with protamine, and in patients with renal dysfunction, the effects can be greatly prolonged and should be avoided in this setting.^{18,20,23} Commonly used LMWHs include enoxaparin and dalteparin.

Heparin-Induced Thrombocytopenia (HIT)

Heparin-induced thrombocytopenia (HIT) is a serious, prothrombotic effect of heparin that develops in 1% to 3% of heparin-treated patients. HIT is an interesting paradigm where an anticoagulant produces an increased risk of thrombosis.^{26,27} The pathophysiology of HIT is due to a heparin-platelet factor 4 immunoglobulin G (IgG) antibody that binds and activates platelets and is associated with increased thrombotic morbidity and mortality.^{26,28} HIT should be suspected whenever the platelet count drops >50% from baseline after starting heparin (or sooner if there was prior heparin exposure) and/or new thrombosis occurring during, or soon after, heparin treatment, with other causes excluded. When HIT is strongly suspected, with or without complicating thrombosis, heparins should be discontinued, and a nonheparin alternative anticoagulant such as a direct thrombin inhibitor (argatroban) should be initiated immediately.^{26,29,30} Bivalirudin is also commonly used off-label, especially in this setting, and for HIT positive patients requiring extracorporeal membrane oxygenation (ECMO).^{31,32}

SYNTHETIC XA INHIBITORS (FONDAPARINUX)

Fondaparinux, a synthetic pentasaccharide with specific antiXa activity, has a long half-life with renal clearance and should be avoided in patients with renal dysfunction.¹⁸ Because of this, it is not commonly used in an ICU setting.

DIRECT THROMBIN INHIBITORS: PARENTERAL AGENTS

An important major class of anticoagulants used primarily for HIT or HIT patients suspected to need anticoagulation are the direct thrombin inhibitors that include bivalirudin, argatroban, and desirudin. Lepirudin is no longer available clinically. All of these parenteral direct thrombin inhibitors also vary in their binding affinities for thrombin and immunogenicity. All of the agents, except argatroban, are polypeptides, so there is a potential but rare risk for antibody formation and hypersensitivity responses.¹⁶ Bivalirudin and argatroban are most often used in an ICU setting and will be considered separately.

Bivalirudin

Bivalirudin is a polypeptide with a molecular weight ~4000 da, approved as an anticoagulant for patients undergoing PCI with provisional use of glycoprotein IIb/IIIa inhibitor, with or at risk of HIT or HIT and thrombosis syndrome undergoing PCI, and with unstable angina undergoing percutaneous transluminal coronary angioplasty (PTCA).³²⁻³⁴ It has also been used off-label as a replacement for heparin with ECMO. With normal renal function, the half-life is ~20 minutes but can be prolonged in patients with renal dysfunction.

Argatroban

Argatroban is an injectable, synthetic, small-molecular-weight (~500 da) direct thrombin inhibitor approved for prophylaxis or treatment of thrombosis in adult patients with HIT or as an anticoagulant in adult patients with or at risk for HIT undergoing PCI. However, for PCI, bivalirudin is currently used in this setting. The half-life is 40-50 minutes, and levels are not affected by renal dysfunction.³⁵ Patients with HIT often also present with acute renal failure, and all of the other agents used for acute HIT therapy are proteins that are renally eliminated. Argatroban is hepatically eliminated so no dose adjustments are required in patients with renal dysfunction. Also antigenicity is not an issue due to its low molecular weight.³⁶ We reported a study of 87 suspected HIT patients in the cardiothoracic ICU of which 47 patients (54%) were treated with argatroban, and 40 patients (46%) were not treated with argatroban. We concluded that clinical suspicion of HIT as detected by clinical probability score and thrombotic complications

should prompt immediate cessation of heparin and initiation of an alternative anticoagulant such as argatroban.³⁷

Desirudin

Desirudin (another recombinant hirudin) is approved in the United States for the prophylaxis of DVT, which may lead to PE in patients undergoing elective hip replacement surgery. Of note, desirudin has also been studied extensively for in patients with stable angina undergoing PTCA. Because desirudin is primarily eliminated by the kidneys, patients with renal impairment require monitoring, and activated partial thromboplastin time (aPTT) can be used. However, this agent is seldom used, especially with all of the newer oral anticoagulation agents available.¹⁸

ORAL ANTICOAGULANTS

Vitamin K Antagonists (VKAs): Warfarin

Warfarin is the only oral VKA agent available in the United States.¹⁸ Warfarin is an effective anticoagulation agent by inhibiting vitamin K epoxide reductase that converts the vitamin K-dependent coagulation proteins (factors II [prothrombin], VII, IX, and X) to their active form as a posttranslational modification. One of the reasons that warfarin's onset is so slow is that it takes several days to decrease coagulation factors to the ~20% to 40% level that is required for a therapeutic INR of 2-3.

Managing warfarin in the ICU setting is complicated and often bridged initially. However, in the bleeding patient, vitamin K will not immediately reverse the anticoagulant effect, and additional therapies are needed as detailed in the guidelines for perioperative management by Douketis in the ACCP guidelines and summarized in Perioperative Management of Antithrombotic Therapy.³⁸ The ACCP guidelines also recommend use of a four-component prothrombin complex concentrate (e.g., Kcentra/Beriplex, CSL Behring [King of Prussia, PA]; or Octaplex, Octapharma [Lachen, Switzerland]) for urgent warfarin reversal when required for bleeding or surgical interventions.³⁸ Additional considerations for warfarin reversal are reviewed below.

New Oral Agents: Apixaban, Dabigatran, Edoxaban, and Rivaroxaban

The new target-specific oral anticoagulation agents have a rapid onset with therapeutic anticoagulation within hours of administration.³⁹ Dabigatran is an oral direct thrombin inhibitor, and apixaban, edoxaban, and rivaroxaban are direct factor Xa inhibitors similar to LMWH but independent of antithrombin.¹⁸ Edoxaban has been recently approved and will not be further discussed. The new agents require dose adjustments for renal failure and will be considered separately.^{18,40}

Apixaban

Apixaban is a factor Xa inhibitor anticoagulant approved for reducing the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation and for the prophylaxis of DVT, which may lead to PE in patients who have undergone hip or knee replacement surgery, for the treatment of DVT and PE, and for the reduction in the risk of recurrent DVT and PE following initial therapy. If bleeding occurs and measurement of its effects is needed, then using a specific calibrated anti-Xa assay, similar to what is used for LMWH, is needed. However, measuring the effects of the Xa inhibitors can be difficult.⁴¹ The formulation can be crushed and given through a feeding tube if needed in the ICU setting.

Dabigatran Etxilate

Dabigatran etexilate is an oral, direct thrombin inhibitor currently approved to reduce the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation, for the treatment of DVT and PE in patients who have been treated with a parenteral anticoagulant for

5 to 10 days, and to reduce the risk of recurrence of DVT and PE in patients who have been previously treated. Dabigatran has a rapid onset of action and no requirement for routine coagulation monitoring. Dabigatran's effects can be measured best by tests similar to any direct thrombin inhibitor, including aPTT values, thrombin times, diluted thrombin times, or ecarin clotting times.⁴⁰ A specialized assay that uses a diluted thrombin time is helpful for specific measurement of levels when needed and sensitive to lower levels. However, the aPTT is still a good screening test.⁴² Dosing should also be adjusted for patients with renal dysfunction. The capsule is specially formulated and cannot be altered or crushed for administration in an ICU setting. A specific monoclonal antibody is in clinical trials for acute reversal of dabigatran and will be discussed later.⁴³

Rivaroxaban (Xarelto)

Rivaroxaban is a direct-acting oral factor Xa inhibitor, which unlike heparins, does not require antithrombin.⁴² Rivaroxaban has the broadest indications of all of the new agents that include reduction of the risk of stroke and systemic embolism in patients with nonvalvular atrial fibrillation; for the treatment of DVT and PE and for the reduction in the risk of recurrence of DVT and of PE; and for the prophylaxis of DVT, which may lead to PE in patients undergoing knee or hip replacement surgery. If bleeding occurs and measurement of its effects are needed, then using a specific calibrated anti-Xa assay, similar to what is used for LMWH, is needed.⁴¹ The formulation can be crushed and given through a feeding tube, if needed, in the ICU setting.

ICU Management of the Oral Anticoagulants

In the ICU, oral therapy often is not feasible, and parenteral agents need to be considered. In renal failure, heparin and argatroban are most often used, and bivalirudin offers an alternative, but all of these agents require monitoring. However, for urgent reversal or management of the bleeding patients, significant concerns have been expressed about the new agents, but despite the extensive use of LMWH in the ICU, there is no antidote available and it accumulates in renal failure.
